Preface to Developmental Psychopathology, Second Edition

It has been over a decade since the first two volumes of *Developmental Psychopathology* were published. These volumes were extremely well received: They have been highly cited in the literature and they have served as a valuable resource for researchers and practitioners alike. The expansion of the second edition of *Developmental Psychopathology* from two to three volumes speaks to the continued growth of the field, as well as to the ascendance of theory and research in the area of neuroscience informed by a developmental perspective.

There can be no doubt that the discipline of developmental psychopathology has grown significantly in a relatively short period of time. The more than 30 years that have elapsed since the initiation of the Schizophrenia high-risk projects (Garmezy & Streitan, 1974) have been marked by significant contributions to the field. Noteworthy among these are the publication of Achenbach's (1974) first text, Rutter and Garmezy's (1983) chapter in the *Handbook of Child Psychology*, and the continued growth of the journal *Development and Psychopathology*, including the Millennium Special Issue entitled *Reflecting on the Past and Planning for the Future of Developmental Psychopathology* (Cicchetti & Sroufe, 2000). A not insignificant contributor to this rapid growth can be found in the very definitional parameters of the discipline. Theorists and researchers in the field of developmental psychopathology use a lifespan framework to elucidate the many factors that can contribute to the development of mental disorders in individuals at high risk, as well as those operative in individuals who have already manifested psychological disturbances or who have averted such disorders despite their high risk status. In essence, a developmental psychopathology perspective provides a broad, integrative framework within which the contributions of diverse disciplines can be incorporated and enhanced (Cicchetti & Sroufe, 2000). Thus, rather than having to develop new theories and methods, those

working within a developmental psychopathology framework can build on and extend previously established traditions. The ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary research will expedite growth within the field of developmental psychopathology.

As with the previous edition, the current volumes were not organized exclusively around thematic psychiatric disorders. Rather, authors were encouraged to explore developmentally relevant theories, methods of assessment, and domains of functioning. Although many chapters do address specific psychiatric disorders, it is the processes that contribute to the emergence of psychopathology that are emphasized rather than the psychiatric disorders per se.

Volume I, *Theory and Method* presents various approaches to understanding developmental influences on risk and maladaptation. As previously, the volume begins with an explication of the discipline of developmental psychopathology. Within this chapter, a number of significant advances within the field are noted, including the increased attention to processes and mechanisms, the use of multiple levels of analysis, the rise of developmental neuroscience, and the evolution of translational research paradigms. Chapters address a range of topics, including approaches to diagnoses of disorders, developmental epidemiology, diverse theoretical perspectives, various contextual issues, and new frontiers in statistical techniques for developmental phenomena. The volume concludes with a chapter on prevention and intervention.

Volume II, *Developmental Neuroscience*, was added to acknowledge the significant growth in this area since the publication of the first edition of this *Handbook*. Given the seminal historical role that neuroscience played in the emergence of developmental psychopathology (Cicchetti, 1990; Cicchetti & Posner, 2005), it is only fitting that developmental neuroscience has both informed and been informed by developmental psychopathology theorizing.

Neural plasticity, brain imaging, behavioral and molecular genetics, stress and neurobiology, immunology, and environmental influences on brain development are covered in this volume.

Volume III, *Risk, Disorder, and Adaptation* presents various perspectives on contributors to disorder. For example, chapters address the role of social support, family processes, and early experience on adaptation and maladaptation. Other chapters address specific disorders, including mental retardation, language disorders, Autism, disorders of attention, obsessive-compulsive disorders, Tourette's syndrome, social anxiety, Schizophrenia, anti-social disorders, substance abuse, and dissociative disorders. A number of chapters on resilience despite adversity also are included. The volume concludes with a chapter on stigma and mental illness.

All authors were asked to conclude their chapters with discussions of future research directions and needs. Thus, these volumes serve not only to highlight current knowledge in the field of developmental psychopathology, but also to suggest avenues to pursue for progress to continue. In particular, it is increasingly important to incorporate multiple-levels-of-analysis approaches when investigating maladaptation, psychopathology, and resilience (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002). The examination of multiple systems, domains, and ecological levels in the same individuals over developmental time will yield a more complete depiction of individual patterns of adaptation and maladaptation. Moreover, such methods are likely to be extremely valuable in elucidating how interventions may affect brain-behavior relations (see, e.g., Caspi et al., 2002, 2003; Cicchetti & Posner, 2005; Fishbein, 2000; Goldapple et al., 2004; Kandel, 1979, 1998, 1999). Such endeavors could result in significant progress toward understanding psychopathology, highlighting efficacious interventions, and ultimately decreasing the burden of mental illness (Cicchetti & Toth, in press).

I now turn to more personal considerations. Although Donald Cohen is no longer with us, he worked closely with me as we developed our plans for the second edition of *Developmental Psychopathology*. Given our collaboration on the first edition of the volumes and our discussions leading up to the publication of these volumes, I thought it only fitting that he be listed as my coauthor. I believe in my heart that Donald would be pleased to have his name affiliated with these volumes and when I shared this plan with his wife, Phyllis, she gave her enthusiastic endorsement. However, I hasten to add that, unfortunately, Donald's illness and untimely death precluded his active involvement in editing the chapters in these volumes. Thus, despite our many

conversations as the plan for these volumes unfolded, I alone am responsible for the final editing of all chapters.

In closing, I want to dedicate these volumes to my dear friend, Marianne Gerschel. Marianne is a true visionary and she has contributed significantly to my work in the area of developmental psychopathology. Without her belief in the value of this field, my efforts and accomplishments would have been greatly compromised.

Finally, as I write this preface, I am ending a significant era in my life. After more than two decades as the director of Mt. Hope Family Center, I am leaving Rochester to accept a position at the Institute of Child Development, University of Minnesota. There I will be the director of an interdisciplinary center that will emphasize a multiple-levels-of-analysis approach to research and intervention in developmental psychopathology.

This transition is difficult, as Mt. Hope Family Center and my colleagues there have contributed greatly to the growth and development of the field of developmental psychopathology. It is reassuring to know that Mt. Hope Family Center will continue to build upon a solid foundation under the capable directorship of my long-time collaborator and friend, Sheree L. Toth. Although I welcome the new opportunities and challenges that await me, I cannot help being a bit sad to leave. My spirits are buoyed by the knowledge that my work at Mt. Hope Family Center will continue and by my excitement at returning to my roots at the Institute of Child Development where I will have both University and community support to use the field of developmental psychopathology to extend my vision for helping disenfranchised individuals and families throughout the nation and the world.

In recent years, the criticality of undertaking collaborations between scientists from diverse disciplines has increasingly been noted in the literature (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002; Pellmar & Eisenberg, 2000; Rodier, 2002). Two fields of inquiry that epitomize the movement toward interdisciplinary approaches to the investigation of brain-behavior relations in normality and psychopathology are neuroscience and developmental psychopathology (Cacioppo, Berntson, Sheridan, & McClintock, 2000; Cicchetti & Cannon, 1999a, 1999b; Cicchetti & Posner, 2005; Cicchetti & Tucker, 1994b; Cicchetti & Walker, 2001, 2003; Cowan & Kandel, 2001).

Several authors (Albright, Jessell, Kandel, & Posner, 2000; Cowan, Harter, & Kandel, 2000; Kandel & Squire, 2000) have described the unprecedented growth and achievements in the fields of neuroanatomy, neurochemistry, and neurophysiology that have taken place over the past half century. Despite the successes of research in these discrete areas, the present-day excitement engendered by neurobiological research emanates from the integration of several previously independent disciplines into one interdisciplinary intellectual framework known as neuroscience (Albright et al., 2000; Cowan et al., 2000; Kandel & Squire, 2000).

Cowan and colleagues (2000) reviewed the historical roots, as well as the twentieth-century phases of growth, of neuroscience. In the latter part of the nineteenth and the early decades of the twentieth centuries, a number of landmark discoveries occurred, each of which made a significant contribution to one or another of the long-established disciplines of neuroanatomy or neurophysiology. However, Cowan et al. (2000) note that none of these discoveries transcended traditional disciplinary boundaries, the defining feature of the contemporary field of neuroscience.

Kandel and Squire (2000) concluded that the modern cellular science of the nervous system was based on two fundamental discoveries: the neuron doctrine and the ionic hypothesis. Wilhelm His's description of the axon as an outgrowth from the immature nerve cell was an important step toward the formulation of the neuron doctrine. Evidence revealing that there was a discontinuity from neuron to neuron emanated from four scientific areas—embryology, histology, physiology, and pathological anatomy. The demonstration by Spanish neuroscientist Ramon y Cajal (1959) that nerve fibers have terminal structures that contact with other nerve cells but do not fuse with them—that they are contiguous rather than continuous—provided critical support for neuronal development. Ramon y Cajal established the neuron doctrine after demonstrating that the brain was composed of discrete cells called neurons that were thought to serve as elementary signaling units. In Ramon y Cajal's time, investigations of neurogenesis were conducted in the field of histology. In contemporary neuroscience, the focus has been on the molecular and cellular mechanisms involved in neuronal development. The ionic hypothesis, proffered by Alan Hodgkin, Andrew Huxley, and Bernard Katz in the late 1940s, explained the resting and action potentials of nerve cells in terms of the movement of specific ions, thereby enabling the nervous system to be comprehended in terms of physiochemical principles common to all of cell biology (Kandel & Squire, 2000).

The 1950s and 1960s witnessed the integration of neuroanatomy, neuropharmacology, neurochemistry, and behavioral science into neuroscience (Cowan et al., 2000). In early 1978, the inaugural issue of the *Annual Review of Neuroscience* was published, heralding the next phase of a multidisciplinary approach to the nervous system: the emergence of molecular neuroscience, the application of recombinant DNA technology and molecular genetics to neurobiological problems, and the unification, within a common intellectual framework, of neuroscience with the rest of the biological sciences (Ciaranello et al., 1995; Landner & Weinberg, 2000).

The emergence of molecular neuroscience enabled the field of neuroscience to surmount the intellectual barricades that had separated the study of brain processes, couched firmly in neuroanatomy and electrophysiology, from the remainder of the biological sciences, based more in biochemistry and cellular and molecular biology (Alberts et al., 1994; Cowan et al., 2000; Kandel & Squire, 2000). Kandel and Squire (2000) concluded that the modern molecular era of developmental neuroscience began in 1956 when Levi-Montalceni and Cohen isolated nerve growth factor (NGF), the first peptide growth factor to be discovered in the nervous system. The third phase in the evolution of neuroscience as a discipline, cognitive neuroscience, occurred during the 1980s and was marked by its incorporation of the methods of cognitive psychology, thereby bringing together the investigation of mental activity with the biology of the brain (see Gazzaniga, 2004; Kandel & Squire, 2000; Nelson & Bloom, 1997; Posner & DiGirolamo, 2000).

Similar to the historical growth witnessed in neuroscience, Cicchetti (1990) described developmental psychopathology as a new discipline that is the product of an integration of various disciplines, including genetics, embryology, neuroscience, epidemiology, psychoanalysis, psychiatry, and psychology, the efforts of which had previously been separate and distinct. Multiple theoretical perspectives and diverse research strategies and findings have contributed to developmental psychopathology. In fact, contributions to this field have come from virtually every corner of the biological and social sciences (Cicchetti & Sroufe, 2000).

GOALS OF THIS CHAPTER

Because developmental psychopathology and neuroscience share fundamental principles, the connection between neuroscience and developmental psychopathology can provide a compelling framework to support the study of normal and abnormal neurobiological development. In this chapter, we examine neurobiological development in normal and illustrative high-risk conditions and mental disorders. Moreover, we review relevant findings on neural plasticity and their potential contributions to the understanding of psychopathology and adaptive functioning. Additionally, we discuss the neurobiological correlates of, and contributors to, resilient adaptation. Finally, we conclude with a discussion of future work that can advance knowledge and inform prevention and intervention efforts in this area.

PRINCIPLES OF DEVELOPMENTAL NEUROSCIENCE AND DEVELOPMENTAL PSYCHOPATHOLOGY

One of the central tenets of the discipline of developmental psychopathology—that the study of normality and pathology are mutually informative—also is embraced by developmental neuroscientists (see, e.g., Cicchetti, 1990; Goldman-Rakic, 1987; Johnson, 1998). Developmental psychopathologists and developmental neuroscientists both emphasize the importance of understanding normal developmental patterns so that we can begin to investigate the ways in which deviant development may eventuate (Cicchetti & Posner, 2005). In addition, a firm knowledge base of normative biological and psychological developmental processes is essential to establish operational criteria for resilient functioning in individuals who have experienced significant adversity (Luthar, Cicchetti, & Becker, 2000).

Moreover, scientists in these two fields have long argued that one can gain valuable information about an organism's normal functioning by studying its abnormal condition (Cicchetti, 1984, 1990; Luria, 1980; Sroufe, 1990). Furthermore, developmental psychopathologists and neuroscientists both contend that the investigation of “experiments of nature” can affirm, challenge, and augment existing etiological theories of normal and abnormal developmental processes (Cicchetti, 2003; O'Connor, 2003).

Nearly half a century ago, the embryologist Paul Weiss enunciated a view that foreshadows present-day thinking on the importance of examining the interrelation between normal and abnormal development: “Pathology and developmental biology must be reintegrated so that our understanding of the ‘abnormal’ will become but an extension of our insight into the ‘normal,’ while . . . the study of the ‘abnormal’ will contribute to the deepening of that very insight. Their common problems should provide foci for common orientation, so that, as they advance in joint directions, their efforts may supplement and reinforce each other to mutual benefit” (Weiss, 1961, p. 50).

Scientists within the field of neuroscience have a long history of investigating pathological phenomena to elucidate the nature of normal developmental processes (see Cicchetti, 1990, for an illustrative review). Some contemporary exemplars from neuroscience regarding how the study of atypical conditions can enhance our understanding of basic normal developmental processes include: the investigation of human microcephaly to gain insight into normal neurogenesis (Woods, 2004); the conduct of molecular genetic studies of human brain malformations in order

to aid in the discovery of molecules that regulate central nervous system neuronal migration (Ross & Walsh, 2001); and neuropsychological investigations that demonstrate distinctive developmental differences following early damage to diverse areas of the prefrontal cortex and that support the critical role that the prefrontal cortex plays in the ongoing maturation of socioemotional, cognitive, and moral development (Diamond, Prevor, Callender, & Druin, 1997; Eslinger, Flaherty-Craig, & Benton, 2004).

THE BRAIN AS A DYNAMIC, SELF-ORGANIZING DEVELOPMENTAL SYSTEM

In present-day neuroscience, information in the brain is viewed as being represented and processed by distributed groups of neurons that maintain a functional interconnection based on experiential demands rather than by a strictly predetermined scheme (Black & Greenough, 1992; Courchesne, Chisum, & Townsend, 1994; Johnson, 1998). Because levels of organization and processes are reciprocally interactive, it is difficult, if not impossible, to impute ultimate causation to one level of organization over another (Cicchetti & Cannon, 1999a; Thelen & Smith, 1998).

It has become increasingly clear that the investigation of developmental processes, typical and atypical, often necessitates the simultaneous examination of individuals utilizing a multiple-levels-of-analysis approach (Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002; Cicchetti & Toth, 1991; Gottlieb, Wahlsten, & Lickliter, 1998; Pellmar & Eisenberg, 2000; Thelen & Smith, 1998). In keeping with the historical tradition of prior systematizers in the field (Engel, 1977; McHugh & Slavney, 1986), *explanatory pluralism* and *methodological pluralism* have been considered to be the most suitable approaches to comprehend the nature of mental disorder (Cacioppo et al., 2000; Cicchetti & Dawson, 2002; Ghaemi, 2003; Kendler, 2005; Richters, 1997). Neuroscientists increasingly have shifted their emphasis from investigating molecules, membranes, and single neurons and tracts to examining complex neural systems (Edelman, 1987; Kandel, 1998; Thelen & Smith, 1998). In these more contemporary theoretical conceptualizations of brain-behavior relations, the brain is viewed as operating in a plastic and dynamic, self-organizing fashion, and as being less constrained by predetermined “localized” boundaries than previously thought (Cicchetti & Tucker, 1994a; Finger, 1994).

The viewpoint that the nervous system is dynamic is not exclusively a product of modern neuroscientific principles.

For example, in *The Brain of the Tiger Salamander*, C. J. Herrick (1948) restated the point that he had made in several prior publications spanning from 1908 through 1933—namely, that in all phylogenetic investigations of morphogenesis, it is important to keep in mind the conservative factor of stable genetic organization and the more labile influence of the functional requirements. Herrick (1948) contended that any morphology that overlooked the dynamic factors of tissue differentiation in terms of physiological adaptiveness lacks something and is sterile.

Systems theory approaches have historical roots in the investigations of a number of eminent developmental psychobiologists whose work occurred in the 1930s through the 1960s (see, e.g., Kuo, 1967; Lehrman, 1953; Schneirla, 1957). In contemporary developmental psychobiology, the system viewpoint is represented most elegantly in the writings of Gilbert Gottlieb (1983, 1992; Gottlieb et al., 1998).

SELF-ORGANIZATION

One of the main principles of systems theory (von Bertalanffy, 1968) is that organisms exist in a state of disequilibrium (i.e., dynamic stability) and participate in and seek out stimulation, thereby playing an active role in the construction of their own development. Thus, organisms are capable of *self-organization*—a reorganization that alters a system in an adaptive fashion when it is subjected to new constraints.

Similarly, several historically prominent developmental theorists maintain that disequilibrium enables individuals to exhibit change and flexibility throughout ontogenesis (Piaget, 1971; Werner, 1957). Such nonequilibrated systems assume a number of special properties including the ability to self-organize into patterns and nonlinearity or sensitivity to initial conditions (Prigogine, 1978). Cicchetti and Tucker (1994a) suggested that the concept of self-organization might serve as one of the mechanisms whereby individuals function in a resilient fashion despite experiencing great adversity. Furthermore, Cicchetti and Tucker (1994a) conjectured that self-organization might be a mediator of neural plasticity throughout the life course.

In self-organizing brain development, some regions of the brain serve to stabilize and organize information for other areas, whereas other regions utilize experience to fine-tune their anatomy for optimal function (Singer, 1995). In this manner, individuals can use the interaction of genetic constraints and environmental information to self-organize their highly complex neural systems. Accordingly, each individual may follow a potentially unique and partly self-determined developmental pathway of brain building.

Fundamental mechanisms of self-regulation are provided by brainstem neuromodulatory projection systems (Cicchetti & Tucker, 1994a). With widespread projections to cortical and subcortical targets, the neuromodulator systems serve as focal control points for regulating neural activity. By directing neural activity, it is expected that the neuromodular systems of the developing brain direct the activity-dependent pruning of the synaptic architecture. Each neuromodular system appears to tune neural and behavioral activity in a specific way and this specificity of effect may have direct implications for the control of neural plasticity.

THE DEVELOPING BRAIN

Wilhelm His was perhaps the preeminent contributor to research on the histogenesis of the central and peripheral nervous systems in the nineteenth century. His's discoveries included finding that changes in the shape of cells were involved in the folding of tissues, such as the neural plate. His also discovered the neural crest and the origin of the peripheral nervous system, and demonstrated that cranial and spinal ganglia are formed by cells that migrate from the neural crest (Jacobson, 1991). Moreover, His found that nerve cells originate by mitosis of stem cells near the ventricle of the neural tube rather than in the cerebral cortex itself (Jacobson, 1991). Furthermore, the concept of cell migration in the vertebrate central and peripheral nervous systems was discovered by His, initially through his observations on the origins of the peripheral nervous system from the neural crest and subsequently by his discovery that neuroblasts migrate individually from the ventricular germinal zone to the overlying mantle layer of the neural tube (Jacobson, 1991).

In 1904, His published a monograph in which he summarized more than 3 decades of his experimental work on the development of the embryonic nervous system of humans. In this monograph, he delineated the basic principles of neurogenesis for vertebrates in general. His's ideas provide the framework for the vast majority of subsequent studies of the nervous system (Sidman & Rakic, 1982). The virtual identity of the neural plate and the neural tube in all vertebrates provided suggestive evidence for the operation of very similar mechanisms in central nervous system development throughout phylogenesis.

In subsequent years, important contributions have been made by a number of investigative teams that elucidated the extraordinary diversity, organizational complexity, and precision of connections between cells in the nervous system of both vertebrates and invertebrates. Among these

most prominent historical contributions to the early understanding of neural development were those of Ramon y Cajal in Madrid, Hochstetter in Vienna, and scientists at the Moscow Brain Institute (1935–1965) and the Carnegie Institute in Baltimore (1942–1962; see review in Sidman & Rakic, 1982).

Cowan (1979) concluded that in the development of any part of the brain, eight major stages can be identified: (1) the induction of the neural plate; (2) the localized proliferation of cells in different regions; (3) the migration of cells from the region in which they are generated to the places where they ultimately reside; (4) the aggregation of cells to form identifiable parts of the brain; (5) the differentiation (expression) of the immature neurons; (6) the formation of axonal pathways and synaptic connections with other neurons and the onset of physiological function; (7) the selective death of certain cells; and (8) the elimination of some of the connections that were initially formed and the stabilization of others. As Steingard and Coyle (1998) noted, these stages proceed in a stepwise fashion following a genetically encoded plan that is influenced by environmental events. Specifically, within each of these phases there are parallel processes of metabolic differentiation and maturation. Genes that take their regulatory cues from the immediate neurochemical (and experiential) environment regulate the onset and offset of each stage.

Moreover, each stage of brain development is dependent on the successful completion of the preceding stages. Alterations in these processes can eventuate in aberrant neural development, connectivity, or function (Rakic, 1996; Steingard & Coyle, 1998). In general, early disruption in the neurodevelopmental process is associated with a greater and more diffuse pathology (Nelson, 2000a; Volpe, 1995), while later disruptions in this process are associated with less severe pathology and more discrete neurological lesions (Steingard & Coyle, 1998). For example, if neuronal migration is disrupted, then abnormalities in cell position result. When this occurs, the neurons are said to be ectopic or heterotopic (Nowakowski, 1987). Likewise, delaying, extending, shortening, or blocking either the *progressive* (e.g., synaptogenesis and neuronal maturation) or *regressive* (e.g., cell death and synaptic pruning) events in the neurodevelopmental process exerts varying effects on structure-function relations, genetic regulatory processes, and on the emergence of later neurodevelopmental events that are dependent on earlier events (Keshavan & Hogarty, 1999; Nowakowski, 1987; Nowakowski & Hayes, 1999; Steingard & Coyle, 1998).

In 1939, Conel suggested that most cortical neurons in the human cerebrum were generated prenatally. More so-

phisticated marking of cells has enabled neuroscientists to permanently date DNA cell replication and thereby provide direct evidence and precise time of neuron data on the origin and termination of corticogenesis in primates (Johnson, 1997; Rakic, 1996, 2002a, 2002b). By utilizing the same marking of DNA replication technique in humans, we now know that humans develop their full complement of neurons mainly during the 4th, 5th, and 6th prenatal months (Rakic, 1981). The onset of corticogenesis in humans is approximately at 6 prenatal weeks (Rakic, 1996). Through a more sophisticated autoradiographic analysis, Sidman and Rakic (1982) confirmed His's earlier discovery that all neurons destined for the neocortex were produced in the proliferative zone near the cerebral ventricle.

In the proliferative zone, precursor cells divide asynchronously; their nuclei move from the ventricular surface to synthesize DNA and then return to the surface to undergo another mitotic cycle (Rakic, 1996). There are two proliferative sites: (1) the ventricular zone, which contributes to cell proliferation and division in phylogenetically older brain structures and (2) the subventricular zone, which contributes to cell proliferation and division in more recently evolved brain structures, such as the neocortex. These two proliferative zones generate separate glial and neuron cell lines and give rise to different forms of migration, the process whereby neuronal cell bodies are displaced from their last cell division in the proliferative zone to their final destination in the mature brain (Johnson, 1997; Rakic, 1988a, 1988b).

In 1874, His inferred the phenomenon of neuronal cell migration by analyzing the fixed brains of human embryos; however, more sophisticated autoradiographic techniques have led to the discovery of the underlying cellular and molecular mechanisms of migration (Hatten, 1999; Price & Willshaw, 2000; Sidman & Rakic, 1982). There are two types of cell migration: tangential and radial. In *tangential migration*, once cells are generated they are passively displaced and pushed further away from the proliferative zone by more recently born cells in a so-called "outside-in" gradient. This tangential form of migration occurs at later developmental stages of the prenatal brain and gives rise to brain structures, such as the thalamus, dentate gyrus of the hippocampus, and many regions of the brain stem. In contrast, in *radial migration*, the most recently born cell actively moves beyond previously generated cells to create an "inside-out" gradient. This radial form of migration is visible during early stages of prenatal brain development and is found in the cerebral cortex and in some subcortical areas that have a laminar (layered) structure.

The area-specific features in the human adult neocortex are not evident in the immature cortical plate; rather, they emerge gradually over ontogenesis (Rakic, 1988b). The cells of the neocortex are not committed to differentiate the area-specific architectural and connectional features that distinguish neocortical areas in the adult at the time the neocortical plate is assembled during embryogenesis (Nowakowski, 1987; Sidman & Rakic, 1982; Steingard & Coyle, 1998). There are two primary models of cortical area differentiation that have been put forward in the literature (Johnson, 1997). Rakic (1988a, 1988b) has proposed the *protomap* hypothesis, a model whereby future cytoarchitectonic areas are thought to be genetically specified in the neuroepithelium and recapitulated in the developing cortical plate by a point-to-point migration along a radial glial scaffolding. In this “radial unit hypothesis,” Rakic (1988a, 1988b) contends that the neuroepithelium is genetically programmed to generate area-specific cohorts of cortical plate neurons and that the relative positions and sizes of areas of the cerebral cortex are prespecified. Rakic’s protomap hypothesis applies the same mechanisms of development to areas throughout the cerebral cortex (Johnson, 1997; O’Leary, 1989). Although the programmed emergence of discrete, cytoarchitectonic areas requires an interaction with thalamocortical afferents, the capacity of developing cortical plate neurons to differentiate features normally associated with other areas is conceived as being restricted by their commitment to specific area plates.

A contrasting viewpoint of cortical area differentiation, the *protocortex* model, has been proposed by O’Leary (1989; see also Johnson, 1997, 1998). The protocortex model emphasizes the role of epigenetic influences and applies only to the development of neocortical areas. According to the protocortex model, the neocortical epithelium is not genetically programmed to generate cortical plate cells that are committed to a particular areal fate. Rather, it is hypothesized that the neurons of the neocortical plate have the potential to develop the range of features associated with diverse neocortical areas. The differentiation of the neurons into area-specific connections and architecture requires inputs from thalamic (experiential) afferents to each region (Johnson, 1997; O’Leary, 1989).

In sum, despite their differing emphases, both the protomap and protocortex models recognize contributions from genetic and epigenetic mechanisms in the differentiation of neocortical areas as well as a vital role for thalamocortical afferents in this process. Original to the protocortex model (O’Leary, 1989) is the fact that molecular differences are thought to exist throughout the neocortex and contribute to the process of areal differentiation. Numerous investiga-

tions suggest that afferent inputs, especially thalamocortical afferents, have a fundamental role in regulating the differentiation of area-specific features (see Johnson, 1997). Thus, from the viewpoint of the protocortex model, normal cortical development is believed to enable a considerable amount of cortical plasticity. Cortical regions are capable of supporting a number of different types of representations depending on the nature of their input (Johnson, 1999).

Rakic (1996) discussed that, in the neocortex of the rhesus monkey, synaptogenesis and synapse elimination occur simultaneously and at an equal rate in all cortical regions (see also Goldman-Rakic, Bourgeois, & Rakic, 1997). Conversely, because there are known regional differences in neurobiological development, including timing of maximum brain growth, dendritic arborizations, and myelination of cortical afferents and efferents (Huttenlocher & Dabholkar, 1997; Thompson & Nelson, 2001), it is not surprising that concurrent synaptogenesis does not occur in humans. The prefrontal cortex is the last region to develop (Huttenlocher, 1994, 2002). Thus, competition between and correlated activity within neural networks drives the selective stabilization of some neural connections at the expense of others and leads to the normal parcellation of neural systems into specific structural and functional units (Courchesne et al., 1994).

The normal brain develops from a network of few elements, infrequent interactions among elements, less stability, and less structural and functional differentiation, to one of additional elements, more intricate interactions among elements, greater stability, and increased structural and functional parcellation and specialization (see, e.g., J. W. Brown, 1994; Cicchetti & Tucker, 1994a; Courchesne et al., 1994). In Chapter 3, this *Handbook*, this volume, magnetic resonance imaging studies are reviewed to present a picture of normal and abnormal brain structural development over time.

EXPERIENCE AND BRAIN DEVELOPMENT

One outgrowth of systems theorizing has been a growing acceptance of the viewpoint that neurobiological development and experience are mutually influencing (Cicchetti & Tucker, 1994a; Eisenberg, 1995; Kandel, 1998; Nelson & Bloom, 1997). For example, it has been demonstrated that, just as gene expression alters social behavior (Young, Nilsson, Waymore, MacGregor, & Insel, 1999), so, too, do social experiences exert actions on the brain by feeding back on it to modify gene expression and brain structure, function, and organization (Francis, Diorio, Liu, & Meaney,

1999; Kandel, 1998). Relatedly, changes in the brain may directly exert effects on mental functioning. Conversely, alterations in mental processing can causally affect brain functioning (Bolton & Hill, 1996; Edelman, 2004).

The concept that experience can modify brain structure can be traced back at least to the writings of Cajal (see Cajal, 1913/1959), who, despite his belief that the connections that occurred between neurons unfolded according to a definite plan (i.e., the principle of connection specificity), asserted that the strength and effectiveness of these neuronal connections were not predetermined and that they could be altered by experience (Kandel & Squire, 2000). Likewise, D. O. Hebb (1949) believed that experience could alter brain structure and function and made this viewpoint a central feature of his neuropsychological theory (see Posner & Rothbart, 2004).

In current perspectives, experience is broadly construed to include not only external social and psychological events but also, for example, internal events, such as the effects of psychopathology, trauma, abuse, or injury; the actions of hormones; and the consequences of development and aging (Boyce et al., 1998; Cicchetti & Walker, 2003). For example, an investigation revealed that early life experiences could affect neurogenesis in adulthood. Mirescu, Peters, and Gould (2004) demonstrated that early adversity affects the regulation of adult neurogenesis in the hippocampus. Specifically, rats who experienced maternal deprivation when they were pups did not display the normal decrease in cell proliferation and immature neuron production in the dentate gyrus. This finding was observed despite the fact that these rats had normal hypothalamic-pituitary-adrenal (HPA) axis activation. These results provide suggestive evidence that early adverse experience inhibits structural plasticity via a hypersensitivity to glucocorticoids and impairs the ability of the hippocampus to respond adaptively to stress that occurs in adulthood. Research with humans has similarly demonstrated that adverse early experiences may lead to the development of abnormal brain structures and functioning and sensitize developing neural networks to stressful experiences (Gunnar, 2000). Work with Romanian orphans and with children who have been abused or neglected early in life also has revealed anomalies in their brain structure and functioning (Cicchetti & Curtis, *in press*; Cicchetti & Rogosch, 2001a, 2001b; DeBellis, 2001; Gunnar, Morison, Chisholm, & Schuder, 2001; S. W. Parker & Nelson, 2005b; Pollak, Cicchetti, Klorman, & Brumaghim, 1997). Furthermore, it has been shown that alterations in gene expression induced by learning and by social and psychological experiences produce changes in patterns of neuronal and synaptic connections and, thus, in the func-

tion of nerve cells (Kandel, 1998, 1999; Post, Weiss, & Leverich, 1994). Such neuronal and synaptic modifications not only exert a prominent role in initiating and maintaining the behavioral changes that are provoked by experience but also contribute to the biological bases of individuality, as well as to individuals being differentially affected by similar experiences, regardless of their positive or negative/adverse valence (Cicchetti & Rogosch, 1996; Depue & Collins, 1999; Kandel, 1998).

Mechanisms of Neural Plasticity

Although brain development is guided and controlled to some extent by genetic information (Rakic, 1988a, 1998), a not insignificant portion of brain structuration and neural patterning is thought to occur through interaction of the child with the environment (Greenough, Black, & Wallace, 1987; Nelson, 1999; O'Leary, 1989). As eloquently expressed by Torsten Weisel (1994): "genes controlling embryonic development shape the structure of the infant brain; the infant's experience in the world fine tunes the pattern of neuronal connections underlying the brain's function. Such fine-tuning . . . must surely continue through adulthood" (p. 1647). Relatedly, Nelson (1999) asserted that the fine-tuning of the biological and behavioral systems that occurs beyond the early years of life is more subtle and protracted than that which is manifested in infancy. Moreover, Nelson (1999) stated that the "dramatic changes that occur in the brain long after the child's second or third birthday are in large measure brought about by the experiences the child has with his or her environment" (p. 237).

Recognizing that mechanisms of plasticity are integral to the very anatomical structure of cortical tissue, and that they cause the formation of the brain to be an extended malleable process, neuroscientists and developmental psychopathologists are presented with new avenues for understanding the vulnerability and protective aspects of the brain as contributors to the genesis and epigenesis of psychopathology and resilience (Cicchetti & Tucker, 1994a). Because the mechanisms of neural plasticity cause the brain's anatomical differentiation to be dependent on stimulation from the environment, it is now clear that the cytoarchitecture of the cerebral cortex also is shaped by input from the social environment. Since the human cerebral cortex is only diffusely structured by a genetic plan, and since the eventual differentiation of the cortex is highly reactive to the individual's active coping and "meaning making" in a particular environment, it is very likely that both abnormal and resilient outcomes following the experience of significant adversity would encompass a

diverse range of neural, synaptic, and associative networks that are the physiological underpinnings of many possible individual psychological organizations (cf. Cicchetti & Tucker, 1994a; Curtis & Cicchetti, 2003). As Luu and Tucker (1996) have articulated: "To understand neuropsychological development is to confront the fact that the brain is mutable, such that its structural organization reflects the history of the organism. Moreover, this structure reflects both what is most important to the organism and what the organism is capable of at that particular time" (p. 297). Cortical development and organization should no longer be viewed as passive processes that solely depend upon genetics and environmental input. Rather, corticogenesis and organization should be conceived as processes of self-organization guided by self-regulatory mechanisms (Cicchetti & Tucker, 1994a).

Black, Jones, Nelson, and Greenough (1998) have described brain development as a complex scaffolding of three types of neural processes: gene driven, experience expectant, and experience dependent. Black et al. (1998) conceptualized *gene-driven processes* as being largely insensitive to experience. Gene-driven processes serve to guide the migration of neurons, to target many of their synaptic connections, and to determine their differentiated functions. To protect the development of the brain, much of the basic organization of most nervous systems is thought to be relatively impervious to experience. The recalcitrance to environmental influences during embryonic development was termed *canalization* by Waddington (1966). Black and colleagues (1998) note that this canalization process can be either helpful (e.g., the minimization of experiential effects on embryogenesis can aid survival) or harmful (e.g., in cases of genetic diseases, prenatal brain development proceeds along a maladaptive pathway that is largely resistant to any therapeutic interventions).

Experience-expectant processes correspond roughly to critical or "sensitive" periods and take place in early age-locked sensory system development (Greenough & Black, 1992; Greenough et al., 1987). During experience-expectant periods, the brain is primed to receive particular classes of information from the environment. The brain builds an overabundance of synapses that are then pruned back by experience to a selectively retained subset (Huttenlocher, 1990; Huttenlocher & Dabholkar, 1997). The pruning of synapses appears to be initiated by competitive interactions between neuronal connections such that inactive neural connections are eliminated and synapses that are most actively mediated by experience are selectively maintained (Greenough et al., 1987). In human embryol-

ogy, the pruning process applies to neurons, whereas postnatally it applies predominantly to synapses (Edelman, 1987). In the absence of behavioral and neural activity, cells do not die and circuits do not become pruned in an adaptive way that aids the organism in adapting to the demands of its environment.

Experience-expectant neural plasticity is usually embedded in a developmental program and requires appropriate timing and quality of the information stored for brain development to be normal. Abnormal experience or deprivation during experience-expectant development may exert enduring deleterious effects on brain and behavioral epigenesis (Black et al., 1998). Experience-expectant neural plasticity varies widely across brain systems, eventuating in highly specialized alterations that occur as a function of the timing and nature of the modified experience and the brain systems involved (Bavelier & Neville, 2002). Variations in experience-expectant neural plasticity take place as a function of a number of existing factors, including: (1) differences in the temporal expression of receptors that are necessary for synaptic plasticity; (2) differences in the molecular factors that control the development of various neural pathways; and (3) differences in the degrees of exuberant or redundant early connectivity (Bavelier & Neville, 2002).

In later development, synaptogenesis seems to be generated in response to events that provide information to be encoded in the nervous system. This *experience-dependent* synapse formation involves the brain's adaptation to information that is unique to the individual (Greenough & Black, 1992; Greenough et al., 1987). Because all individuals encounter distinctive environments, each brain is modified in a singular fashion. Experience-dependent synaptogenesis is localized to the brain regions involved in processing information arising from the event experienced by the individual. Unlike the case with experience-expectant processes, experience-dependent processes do not take place within a stringent temporal interval because the timing or nature of experience that the individual engages or chooses cannot be entirely and dependably envisioned. An important central mechanism for experience-dependent development is the formation of new neural connections in contrast to the overproduction and pruning back of synapses often associated with experience-expectant processes (Greenough et al., 1987). Because experience-dependent processes can occur throughout the life span, social interactions, psychotherapy, and pharmacotherapy have the capacity to exert a palliative influence on brains that are afflicted with disorders (Black et al., 1998; Cicchetti, 1996; Cicchetti &

Posner, 2005; Cicchetti & Sroufe, 2000; Cicchetti & Walker, 2001; Goldapple et al., 2004; Mayberg, 2003).

Neural Plasticity: Historical Aspect

In the denouement to his treatise entitled *Degeneration and Regeneration of the Nervous System*, Cajal declared: "Once development is completed, the sources of growth and regeneration are irrevocably lost. In the adult brain, nervous pathways are fixed and immutable; everything may die, nothing may be regenerated" (Cajal 1913/1959, p. 750).

After over a decade of innovative and meticulous research in which he investigated whether the brain was capable of regeneration in animals with injuries to the spinal cord, the cerebellum, or the cerebral cortex, Cajal proclaimed that "the vast majority of regenerative processes described in man are ephemeral, abortive, and incapable of completely and definitely repairing the damaged pathways" (Cajal, 1913/1959, p. 750). Since Cajal's early work, it has been known that there is some axonal regeneration subsequent to spinal cord injury; however, in the experimental conditions that Cajal designed, regeneration was limited and, therefore, not believed to have any functional significance (Stein & Dawson, 1980). Cajal's assertions served as the prevailing dogma for a large portion of the twentieth century. The widespread belief put forward by neuroscientists was that because no new neuron generation was deemed possible, rewiring of existing connections, dendritic branching, and elimination of synaptic connections were the only ways whereby neural plasticity could occur.

It was not until the 1970s that regenerative capacity was demonstrated in the adult mammalian brain. Two types of growth were found to occur in response to nerve injury (Stein & Dawson, 1980). The first is *regenerative sprouting*, a process whereby when the axons of cells are cut and the distal portion begins to degenerate, the remaining stump, including the cell body, begins to form growth cones and regenerate new terminals. In the second, known as *collateral symmetry*, a number of cells innervating a given structure are destroyed and their terminals degenerate. However, the remaining intact cells begin to grow additional new terminals (sprouting) that innervate the target area evacuated by the damaged neurons. As such, the degenerated inputs are replaced by terminals arriving from intact neurons.

In 1975, the eminent neuropsychologist Hans-Lucas Teuber declared that if one is going to have brain damage, then it would be preferable to have it early rather than late in life. Teuber based his conclusion on the findings of Margaret Kennard's experiments on the long-term effects of

brain damage in monkeys of different ages. Kennard (1938) discovered that damage to the adult nervous system resulted in more deleterious and less reversible effects than similar brain damage inflicted during early development. The field's acceptance of the so-called "Kennard principle" led to the belief that little reorganization of function could occur after injury to the mature mammalian nervous system and that most structure-function relations were permanently established during the early years of life. In fact, Teuber's (1975) own studies with humans revealed that improvement in traumatic head injury cases was substantially greater when the brain damage had taken place in an early developmental period. However, scientists in the field had differing interpretations of Teuber's belief that brain damage that occurred later in development would exert more disruptive effects than damage originated earlier in life. Critics noted that the results of the experimental data of Teuber and his contemporaries in the field could be interpreted to indicate that the maturational status of the nervous system at the time of injury must be considered in any explanation of recovery or sparing of function after early brain damage (Stein & Dawson, 1980). Commentators on the aforementioned body of work reasoned that if subjects were tested at a time when the substrate for a particular function had not yet developed, then the function would appear to have been compensated when, in fact, it had never been lost (Isaacson, 1975). Depending on the location of the lesion and the precise timing of the injury, the developing brain can suffer from far more neuronal degeneration than that evidenced in the mature brain. For example, excessive amounts of excitatory amino acids, such as glutamate, produce much more severe lesions in the immature brain than in the adult brain. Thus, there are a number of instances in which early brain damage can be viewed as more disastrous than later brain damage because early lesions often result in the formation of anomalous circuitry and neural pathways as well as reduction in brain size (Black et al., 1998; Isaacson, 1975; Steingard & Coyle, 1998).

Kolb, Forgie, Gibb, Gorny, and Rowntree (1998), in their programmatic enrichment studies on brain plasticity and behavior in rats after brain injury, found that enriched experience could have varying effects upon the brain at different ages. They reported discovering compensatory changes in brain plasticity following brain injury that are similar in kind to those observed when animals learn from experience. Kolb and colleagues (1998) found that experience alters the synaptic organization of the cortex and that these changes in synaptic organization are associated with behavioral changes. The similarity between plastic changes

in the brain in response either to injury or to experience suggests that it is conceivable that there may be basic mechanisms of synaptic change in the mammalian cortex that are used in many forms of neural plasticity (see also Kolb, 1995).

Accordingly, it appears that there are not any simple rules that govern whether neural plasticity occurs following lesions in early life. Most of the early neuropsychological models of the effects of brain lesions were based on work with patients, were predominantly focused on brain localization, and were couched within unidirectional models of causality (i.e., brain lesions were believed to affect behavior, but not vice versa). These early models did not take into account the dynamic interplay that occurs among brain regions and the bidirectional impact that brain and behavior exert upon each other. Modern-day research, conducted predominantly, but not exclusively, with animals, provides suggestive evidence that the mammalian central nervous system possesses much greater potential for producing new neurons and repairing damaged areas than has heretofore been thought (Cicchetti & Tucker, 1994a, 1994b; Curtis & Cicchetti, 2003).

In the developing organism, studies conducted with a variety of species also have revealed that positive or negative early life experiences can modify both brain structure and function. For example, Sur and colleagues (Sur, Garraghty, & Roe, 1988; Sur, Pallas, & Roe, 1990) trained adult ferrets, who had one hemisphere rewired at birth, to discriminate between auditory and visual stimuli that were presented to the normal hemisphere. The results of these experiments provide support for the functional equipotentiality of cortical mapping. Specifically, the findings in the Sur, Garraghty, et al. (1988) and Sur, Pallas, et al. (1990) investigations demonstrate that it is possible to rewire sensory inputs to the thalamus such that processing of auditory stimuli takes place in the primary visual cortex and vice-versa; that is, the cortical field that usually mediates vision could attain a functional organization capable of processing sound, and the cortical field that usually mediates audition could attain a functional organization capable of processing sight.

Sur and colleagues (Sharma, Angelucci, & Sur, 2000) also have demonstrated that, in ferrets whose retinal projections were routed into their auditory pathway, visually responsive neurons in the “rewired” auditory cortex, just as is the case with neurons in the primary visual cortex, were characterized by orientation modules—groups of cells that share a preferred stimulus orientation. Although the orientation tuning of neurons within the “rewired” auditory cortex was comparable to the tuning of cells in the

primary visual cortex, the orientation map was less orderly. Thus, the findings of this investigation reveal that sensory afferent activity profoundly influences diverse components of cortical circuitry.

Finally, the long-held assumption that neural reorganization following injury was restricted to the period of infancy, with only modest neural reorganization possible in the child and adult, has been challenged through research with humans. Results from a number of investigations suggest that reorganization of cortical pathways can occur in the brains of older children and adults (see, e.g., Merzenich, 1998; Merzenich et al., 1996; Tallal et al., 1996). Although the majority of these neural changes to date have been demonstrated in work on sensory or motor pathways (see, e.g., Aglioti, Bonazzi, & Cortese's, 1994, work on phantom lower limb as a perceptual marker of neural plasticity), existing research provides suggestive evidence that cognitive systems (i.e., language) can reorganize beyond infancy (see, e.g., Merzenich et al., 1996; Tallal et al., 1996; also see discussions in Johnson, 1999). Thus, it is becoming quite clear that under certain conditions at least some regions of the brain can incorporate the signature of experience into the structure, function, and organization of the brain.

The process of neural plasticity is influenced by a number of neurotransmitters and growth factors. These growth factors, including nerve growth factor and brain-derived neurotrophic factor, stimulate a variety of cellular effects at the structural and functional levels that eventuate in the promotion of survival and differentiation of responsive neurons. Adaptive alterations in neuroarchitecture may occur throughout life as new synapses form, old ones disintegrate, and new neurite outgrowth occurs. The discovery of brain behavioral plasticity can make important contributions to the understanding of development through demonstrating that neural representations are dynamic processes. Moreover, experimental results that provide evidence of plasticity can give critical insights into the actual processes through which neurobiological development occurs.

Recovery of function following brain injury can be characterized as a maturational process in which the brain is thought to cause the formation of new structures via specialized mechanisms that were triggered by the injury (i.e., *causal epigenesis*; see Johnson, 1999). This viewpoint involves the restriction of fate—that is, biological tissue that initially had many possibilities for subsequent specialization throughout development is reduced to a subset of these possibilities by the injury. In contrast, according to Gottlieb's (1992) *probabilistic epigenesis* framework, brain plasticity may be conceived as a fundamental and inherent

property of the developing brain. From this viewpoint, plasticity is conceptualized as allowing the neural system to retain a number of options for specialization even after brain injury. This process is influenced by neural activity rather than by molecular markers. In humans, neurobiological development is a more prolonged process than in animals, extending well into postnatal life (Nelson & Bosquet, 2000; Spear, 2000; Thompson & Nelson, 2001). Critical aspects of neurobiological development occur after middle childhood (Dahl, 2004; Giedd, 2004; Spear, 2000). Therefore, some degree of functional specialization in the cerebral cortex is likely to be influenced by the child's interaction with the postnatal environment (Johnson, 1999; Johnson et al., 2005). The extremely long juvenile period (neotony) in humans may have evolved, in part, for the primary purpose of shifting cortical specification from genetic to epigenetic control (Cicchetti & Tucker, 1994a).

During the past several decades, scientific research has begun to reveal that, within certain limits, forms of neural plasticity may take place throughout epigenesis and are not limited to early development (Cicchetti & Tucker, 1994b; Hann, Huffman, Lederhendler, & Meinecke, 1998; Kandel & Squire, 2000). The cortex, in fact, appears to be capable of organizational changes throughout the life course of the organism (Cicchetti & Tucker, 1994a; Jacobs, van Praag, & Gage, 2000). For example, Thatcher's (1992, 1994, 1997) work on the development of electroencephalogram (EEG) coherence in humans suggests that cortical organization proceeds in stages that are repeated cyclically over development. Each stage of cortical organization reflects the ongoing and dynamic shaping of cortical circuitry throughout an individual's life span. These periods of EEG coherence are thought to represent rapid synaptic growth within functionally differentiated neural systems. Neural plasticity involves the genetically driven overproduction of synapses and the environmentally driven maintenance and pruning of synaptic connections.

Neuroscientists conceive plasticity as being reflective of anatomic, chemical, or metabolic changes in the brain. Nelson (2000b) stated that neuroanatomic changes illustrate the ability of existing synapses to alter their activity through sprouting new axons, regenerating old ones, or by elaborating their dendritic surfaces. Thus, for example, loss of fibers in an area of the cortex (e.g., the corpus callosum) may eventuate in a reduction of synapses in the affected area that is subsequently compensated for by an influx of thalamic synapses into the vacated space that reestablishes communication between the hemispheres. Nelson (2000b) also defined neurochemical plasticity as the ability of synapses to alter their activity through aug-

menting the synthesis of neurotransmitters or enhancing the response of the postsynaptic receptor to the neurotransmitter. Additionally, Nelson (2000b) delineated fluctuations in cortical and subcortical metabolic activity, for example, at the site of an injury, as another possible sign of neural plasticity.

In most mammalian brain regions, neuronal birth and migration take place during a discrete period of prenatal development, followed several days later by cell death (Rakic, 1988a, 1996, 1998). In contrast, the granule cells of the dentate gyrus in the hippocampus, olfactory bulb, and cerebellum are generated predominantly during the postnatal period (Gould & Cameron, 1996). In addition, stem cells that reside in specialized niches in the brain of adult mammals continuously generate new neurons. The neurons in mammalian brains are born in two germinal regions: the subventricular zone (SVZ) and the subgranular zone (SGZ). The SVZ generates olfactory bulb neurons and the SGZ of the hippocampal formation gives rise to granule neurons of the dentate gyrus (Doetsch & Hen, 2005).

In the early adult, approximately 1% of the total olfactory bulb interneurons are added each day. Approximately 50% of these adult-generated olfactory bulb interneurons die within 15 to 45 days after their birth, after they have developed elaborate dendritic morphology and spines. In contrast to their neurogenesis, the early cell death that characterizes the adult-generated olfactory system is activity dependent. Because olfactory cues are critical for survival, the function of the newly born olfactory neurons may be to help enhance olfactory discrimination (Petreanu & Alvarez-Buylla, 2002). Interestingly, environments that are olfactory enriched enhance the length of time that adult-generated olfactory neurons survive. The increased life span of these neurons also is accompanied by improved performance on olfactory memory tasks; however, it is not known whether the improved performance was due to the newly generated neurons or to existing cells exhibiting enhanced activity (Rochefort, Gheusi, Vincent, & Lledo, 2002). Moreover, these adult-born immature neurons have electrophysiological properties that differ from those of old neurons. The unique excitability and connectivity properties may exert distinct functional consequences on the processing of olfactory information (Doetsch & Hen, 2005).

Approximately 85% of dentate gyrus neurons are generated postnatally; however, their production begins during the embryonic period (Gould & Cameron, 1996). A large population of cells reaches the dentate gyrus without undergoing final division; these precursor cells remain in the dentate gyrus and become the source of granule neurons born in the postnatal period. Granule cells are excitatory

neurons that utilize glutamate as their primary neurotransmitter. A growing body of investigations indicates that excitatory input plays a prominent role in the formation of many neuronal populations.

In fact, in the mature central nervous system pools of progenitor cells appear to proliferate and migrate well into adulthood. For example, Kempermann, Kuhn, and Gage (1998) discovered that neurogenesis continues to occur in the dentate gyrus of senescent mice and can be stimulated when the mice are placed in an enriched environment. Kempermann et al. (1998) found that neurogenesis declined with increasing age; however, stimulation of adult and aged mice by changing from regular housing to an enriched environment that provided opportunities for social interaction, physical activity, and exploration brought about an increased number of survival cells. Furthermore, animals residing in enriched environments had more of their cells differentiate into neurons than did mice housed in standard conditions. These findings suggest that the new neurons were generated in the hippocampal area and that neural plasticity can take place in the aging brain in mice.

Likewise, Gould, Tanapat, McEwen, Flugge, and Fuchs (1998) discovered that new neurons are produced in the dentate gyrus of adult monkeys. Moreover, these investigators found that a single exposure to a socially stressful condition (i.e., a resident intruder unfamiliar adult male conspecific) inhibits the proliferation of granule cell precursors. Cortisol and glucocorticoids control the rate of the development of these new neurons, and it is clear that the existing neurons are not merely reorganizing their connections. Furthermore, the mature central nervous system continues to express an array of molecules that are required for the formation of neuronal networks during embryonic development (e.g., neurotrophic growth factors, embryonic forms of cell adhesion molecules, axon-guidance molecules). The presence of these molecules suggests that the degree of potential network remodeling in the mature central nervous system may be more extensive than generally thought (Lowenstein & Parent, 1999). Thus, although there is currently no unequivocal evidence that the fully developed central nervous system continues to generate new neurons and glial cells everywhere, progenitor cells with the potential to produce new cells are prevalent throughout the mature mammalian central nervous system (Gage, 2000; Lowenstein & Parent, 1999).

Two factors, adrenal steroids and excitatory input, have been identified that regulate the proliferation, migration, and survival of granule neurons during the postnatal period through adulthood. In general, increases in adrenal steroid levels or NMDA receptor activation diminish the rate of

cell proliferation, whereas decreases in adrenal steroid levels or NMDA receptor activation increase the rate of cell production. These results also suggest that decreased neurogenesis associated with increased corticosteroid levels may contribute to age-related memory deficits. Moreover, the finding that the neuronal precursor population in the dentate gyrus remains stable into old age, but that neurogenesis is slowed by high levels of adrenal steroids, suggests that these memory deficits may be reversible (Cameron & McKay, 1999). Gould (1999) also reported that activation of serotonergic receptors enhanced neurogenesis in the adult mammalian dentate gyrus. Because adult-generated hippocampal neurons are affected by, and conceivably involved in, learning and memory (Gould, Beylin, Tanapat, Reeves, & Shors, 1999), serotonergic agonists that stimulate granule cell production may prevent memory deficits.

Cells that divide in adulthood do not die soon thereafter. Thus, the cell death that occurs in adulthood does not simply remove cells that were generated incorrectly in adulthood. In fact, because granule neurons that generate in adults survive for at least 1 month and form connections, it is likely that their addition to the granule cell layer has significant functional consequences. In a study that has generated a great deal of controversy in the literature, Gould et al. (1999) discovered that stress does not alter the survival of recently produced neurons in the dentate gyrus. Accordingly, young (immature) adult-generated hippocampal cells may make them uniquely qualified to form synaptic connections rapidly and to participate in the transient storage of information. Furthermore, Gould, Beylin, et al. (1999) found that in order for learning to further enhance the number of new hippocampal neurons, the animal must be engaged in a task for which this brain region is essential. In addition, Gould, Reeves, Graziano, and Gross (1999) discovered that in adult macaque monkeys new neurons are added to the prefrontal, posterior parietal, and inferior temporal cortex. These investigators stated that these new neurons most likely originated in the subventricular zone and then migrated through white matter tracts to the neocortex, where they extended axons. Gould and colleagues hypothesized that the new neurons added to these regions of association cortex might play a role in such functions. Moreover, Gould, Reeves, et al. (1999) conjectured that these immature neurons, which continue to be added on adulthood, are capable of undergoing rapid structural changes and thereby serve as a substrate for learning and memory.

In a subsequent investigation, Gould, Vail, Wagers, and Gross (2001) compared the production and survival of adult-generated neurons and glia in the dentate gyrus, pre-

frontal cortex, and inferior temporal cortex. These investigators found that there were many more cells produced in the dentate gyrus than in either of the two neocortical association areas. Furthermore, a greater percentage of cells in the dentate gyrus expressed a neuronal marker than was the case for cells in either of the neocortical areas. Additionally, Gould and colleagues (2001) discovered that there was a decline in the number of cells approximately 9 weeks after they had been labeled, suggesting that some percentage of the adult-generated new cells may have a transient existence. It is believed that the short-lived nature of these newly generated neurons may make them particularly suited to play a role in learning and memory processes (cf. Gould, Tanapat, Hastings, & Shors, 1999).

The finding of neurogenesis in the neocortex of the adult primate by Gould and her colleagues (1999; Gould, Vail, et al., 2001) astonished the scientific world because, since the writings of His and Cajal, the brain has been considered to be a nonrenewable organ comprised of fully differentiated neurons (Jacobson, 1991; Rakic, 2002b). As previously noted, numerous investigations have found that adult neurogenesis in mammals only occurs unambiguously in the granule cells of the dentate gyrus and the olfactory bulb (Carleton, Petreanu, Lansford, Alvarez-Buylla, & Lledo, 2003; Gage, 2000; Kornack & Rakic, 2001b; Rakic, 1998). Not surprisingly, a number of methodological critiques of the findings of Gould, Reeves, et al. have appeared in the literature (Kornack & Rakic, 2001a; Korr & Schmitz, 1999; Nowakowski & Hayes, 2000; Rakic, 2002a, 2002b). Consequently, the conclusion put forth by some of the great systematizers in the history of developmental neurobiology, that nerve cells that subserve the highest cortical functions are irreplaceable under typical conditions, appears to continue to garner strong support from contemporary neurobiologists.

Neurobiological Pathways to Psychopathology

Just as we described with respect to normal brain development, abnormal neurobiological development also is a dynamic, self-organizing process. However, unlike the case for normal neurobiological development, the final product of abnormal brain development includes a substantial measure of misorganization (Courchesne et al., 1994). Perturbations that occur during brain development can potentiate a cascade of maturational and structural changes that eventually in the neural system proceeding along a trajectory that deviates from that generally taken during normal neurobiological development (Cicchetti & Tucker, 1994a; Courchesne et al., 1994; Nowakowski & Hayes, 1999). Early stressors, either physiological or emotional, may alter the

neurodevelopmental processes of networks, in turn generating a cascade of effects through subsequent developmental periods, conceivably constraining the child's flexibility to adapt to new challenging situations with new strategies rather than with old conceptual and behavioral prototypes (Cicchetti & Tucker, 1994a; Gunnar, 2000; Sanchez, Ladd, & Plotsky, 2001). Accordingly, early psychological trauma may eventuate not only in emotional sensitization (Maughan & Cicchetti, 2002; Rieder & Cicchetti, 1989) but also in pathological sensitization of neurophysiological reactivity (Pollak, Cicchetti, & Klorman, 1998).

Accordingly, abnormal perturbations at one stage of brain development hinder the creation of some new structures and functions, distort the form of later-emerging ones, make possible the construction of ones that normally never become manifest, and/or limit the elaboration and usage of structures and functions that had appeared earlier (Courchesne et al., 1994; Steingard & Coyle, 1998). Eventually, successively more complex, specialized, and stable abnormal neural network configurations and operations develop that differ greatly from antecedent ones (Courchesne et al., 1994). Abnormal competition between, and abnormal correlated activity within, undamaged, as well as damaged, neural networks can drive the abnormal elimination of some connections and neural elements (e.g., remote loss) and the abnormal selective stabilization of others (e.g., aberrant connections are retained or created; Courchesne et al., 1994). Such early developmental abnormalities may lead to the development of aberrant neural circuitry and often compound themselves into relatively enduring forms of psychopathology (Arnold, 1999; Cicchetti & Cannon, 1999b; Nowakowski & Hayes, 1999).

Children whose gene-driven processes construct a disordered brain are likely to experience the world in a vastly different fashion than children who do not have such a strong genetic predisposition (Black et al., 1998). Genes often exert different functional roles in divergent cell types at varying developmental periods (Alberts et al., 1994; Lewin, 2004). Consequently, defects in such genes may trigger a cascade of change that is not confined to a particular neural structure, functional system, or behavioral domain. Even if the subsequent experience-expectant and experience-dependent processes are unimpaired, the experience distorted by the neuropathology is not likely to be appropriately utilized (Black et al., 1998). Thus, children with genetically constructed abnormal brains must have their environments tailored to their specific deficits. If such environmental modifications are not introduced, then these children's subsequent experience-expectant and experience-dependent processes manifest additional aberrations and development

proceeds on an even more maladaptive pathway. Pathological experience may become part of a vicious cycle, as the pathology induced in the brain structure may distort the child's experience, with subsequent alterations in cognition or social interactions causing additional pathological experience and added brain pathology (Cicchetti & Tucker, 1994a). Because experience-expectant and experience-dependent processes may continue to operate during psychopathological states, children who incorporate pathological experience during these processes may add neuropathological connections into their developing brains instead of functional neuronal connections (Black et al., 1998).

Social Experience and Brain Development and Functioning

Empirical evidence gleaned from research with rodents and nonhuman primates has demonstrated that the experience of traumatic events early in life can alter behavioral and neuroendocrine responsiveness, the morphological characteristics of the brain, and the activation of genes associated with negative behavioral and neurobiological outcomes (Sanchez et al., 2001). Moreover, the results of animal studies reveal that early traumatic experiences may exert a harmful impact on the normative developmental processes, which have been shown to be associated with long-term alterations in coping, emotional, and behavioral dysregulation; responsiveness of the neuroendocrine system to stressful experiences; brain structure; neurochemistry; and gene expression (Cicchetti & Walker, 2001; Gunnar et al., 2001). Additionally, research has discovered that depriving rodent infants of adequate social and physical stimulation from their mothers' influences the responsivity of the hypothalamic-pituitary-adrenal axis to stressors in later life (Levine, 1994; Meaney et al., 1996). Furthermore, research with rodents has revealed that naturally occurring variations in maternal care alter the expression of genes whose function is to regulate behavioral and endocrine responses to stress, as well as to modify synaptic development in the hippocampus (Meaney, 2001). In particular, stressors that are imposed on mothers have been shown to increase stress reactivity in their rodent offspring. Thus, quality of parental care is a mediator of the impact that adverse environmental conditions have on neural development in rodents.

Children who are endowed with normal brains may encounter a variety of negative experiences that exert a deleterious effect on neurobiological structure, function, and organization, and contribute to distortions in the way in which these children interpret and react to their worlds (Pollak et al., 1998). In this Handbook, Chapter 4, Volume 3 (Ci-

cchetti & Valentino, 2006), the effect of child maltreatment on the structure and function of neurobiological systems was reviewed. We do not wish to restate the details of the neurobiological studies conducted to date, which demonstrate that different components of brain structure and function, each representing fairly distinct neural systems, are negatively affected by experiencing child maltreatment. Work on acoustic startle, neuroendocrine regulation, event-related potentials (ERPs), and neuroimaging have revealed that the various stressors associated with child maltreatment exert harmful effects on numerous interconnected neurobiological systems. Moreover, the neurobiological development of maltreated children is not affected in the same way in all individuals. Finally, not all maltreated children exhibit anomalies in their brain structure or function. Accordingly, it appears that the effects of maltreatment on brain microstructure and biochemistry may be either pathological or adaptive. Finally, because research with rodents and nonhuman primates has revealed that social experiences, such as maternal care giving behaviors, maternal deprivation, and maternal separation, affect gene expression, as well as brain structure and function (Kaufman & Charney, 2001; Meaney et al., 1996; Sanchez et al., 2001), it is highly probable that child maltreatment affects the expression of genes that impact brain structure, as well as basic regulatory processes (Caspi et al., 2002; Cicchetti & Blender, 2004; Kaufman et al., 2004).

Often, the investigation of a system in its smoothly operating normal or healthy state does not afford the opportunity to comprehend the interrelations among its component systems (see, e.g., Caviness & Rakic, 1978; Chomsky, 1968). Because pathological conditions enable scientists to isolate the components of the integrated system, investigation of these nonnormative conditions sheds light on the normal structure of the system. We next discuss Autism and neurodevelopmental aspects of Schizophrenia as illustrations of how the examination of brain development in mental disorder could provide insights into normal neurobiological processes.

CONTRIBUTION OF BRAIN DEVELOPMENT IN ATYPICAL POPULATIONS TO FURTHERING INSIGHTS INTO TYPICAL NEUROLOGICAL PROCESSES

Autism

Autism is a pervasive developmental disorder characterized by impairments in social communication and inter-

action, a wide range of cognitive and executive functioning deficits, and behavioral stereotypes (American Psychiatric Association, 1994). Over 60 years ago, Kanner (1943), who originally devised the term Autism, suggested that Autism represented a biological dysfunction that reduced the capacity of children to form emotional contact with people. However, a short time later, Kanner revised his conceptual thinking on the etiology of Autism and, along with many others, came to view it as environmentally caused, often believed to be a result of emotionally distant, rejecting parents (Bettelheim, 1967). Fortunately, more recent formulations concerning the etiology of this disorder have emphasized its probable neurobiological and genetic basis (e.g., Courchesne, 1987; Rodier, 2002).

Many neurobiological theories concerning Autism have tended to focus on possible abnormalities of individual brain structures as underlying the observed behavioral and neuropsychological symptoms observed in Autism. A range of theories focused on dysfunction of the brain have implicated abnormalities in nearly every brain system. For example, some theories have been based on animal models of medial temporal lobe dysfunction (e.g., Bachevalier, 1996; Bachevalier & Loveland, 2003), while others have emphasized abnormalities in brain structures, such as the amygdala (e.g., Baron-Cohen et al., 2000), hippocampus (e.g., DeLong, 1992), frontal cortex (e.g., Damasio & Maurer, 1978), and cerebellum (e.g., Courchesne, 1997), as well as other cortical and subcortical regions as fundamental to the etiology of Autism. Until recently, etiological formulations of Autism have failed to take into account the impact of developmental processes and the probable interconnected nature of multiple brain systems at multiple levels of analysis.

Many of the conceptualizations of neural-structural abnormalities underlying the behavioral manifestations of Autism have been based on data obtained through neuropsychological assessment of children with Autism. Such assessments have consistently demonstrated deficits in discrete areas of cognition and executive functioning. One such commonly observed deficit is in attentional functioning, whereby speed of orienting to and processing novel stimuli is reduced in those with Autism (e.g., Akshoomoff, Courchesne, & Townsend, 1997; Townsend, Harris, & Courchesne, 1996), as well as the ability to shift attention (e.g., Wainwright-Sharp & Bryson, 1993). Generally, however, individuals with Autism have been found to have widespread executive functioning impairments that are perhaps a result of the more fundamental attentional deficits found with this disorder (Ozonoff, 2001). Detailed analyses of individual components of executive functioning in those with Autism by Ozonoff and colleagues (2001)

have revealed that individuals with Autism exhibit impairments in cognitive flexibility (Ozonoff, Strayer, McMahon, & Filoux, 1994), but do not show deficits in inhibiting responses (Ozonoff & Strayer, 1997) or in working memory functioning. In addition, Frith (2001) has proposed a somewhat controversial etiological theory of Autism linking deficits in theory of mind ("mind blindness") to abnormalities in a network of brain regions, including the medial prefrontal cortex, areas in the temporal-parietal region, and the temporal poles, all of which are active in nonautistic individuals during theory of mind tasks.

Courchesne and his colleagues have begun to formulate a developmentally based theory of Autism, built upon empirical evidence derived from an examination of the neurodevelopmental course of the whole brain, and in particular the cerebellum and its interconnections with many different brain structures. Across many studies with varying methodologies, the most consistent brain structural abnormality in individuals with Autism occurs in various sites within the cerebellum and limbic system structures (Carper, Moses, Tigue, & Courchesne, 2002). The vast majority of postmortem studies have reported cerebellar pathology, while structural magnetic resonance imaging (MRI) studies consistently find evidence of hypoplasia in the cerebellum (see Courchesne, 1997, for a comprehensive review). The most common postmortem pathology of the cerebellum is a reduction in the number and size of Purkinje neurons (e.g., Bailey et al., 1998; Fatemi et al., 2000; Kemper & Bauman, 1998). Additionally, volumetric MRI studies have consistently indicated reduced size of one or another subregion of the cerebellar vermis (Carper & Courchesne, 2000; Hashimoto et al., 1995). In sum, the strongest and most consistent neuroanatomical evidence points to structural abnormalities in the cerebellum.

However, there is not a clear consensus in the Autism literature concerning the relevance of cerebellar anomalies for a disorder primarily characterized by cognitive, social, and emotional deficits, given the prevailing view that the cerebellum is primarily involved in motor function. But evidence has pointed to cerebellar involvement in a number of cognitive and emotional functions (e.g., G. Allen, Buxton, Wong, & Courchesne, 1997; Gao et al., 1996; Paradiso, Andreasen, O'Leary, Arndt, & Robinson, 1997; Xiang et al., 2003). Thus, a more current, broad view of the role of the cerebellum in overall neurobehavioral functioning creates a more reasonable scenario for implicating abnormalities in this structure as having a central underlying role in Autism.

A functional MRI (fMRI) study of the cerebellum revealed different patterns of cerebellar activation during a simple motor task (pressing a button with the thumb) in a

sample of young adults with Autism compared to a nonautistic control group (G. Allen, Muller, & Courchesne, 2004). In the group with Autism, areas of the cerebellum predicted to be involved in the task exhibited more activation than observed in the control group, and areas of the cerebellum not expected to be associated with this simple motor task were activated in the group with Autism but not in the control group. The investigators concluded that the pattern of functional activation found strongly suggested that the observed functional differences were a reflection of the anatomic abnormalities (i.e., reduced cerebellar volume) found in the persons with Autism.

These authors hypothesize that many of the motor deficits commonly seen in individuals with Autism (e.g., balance problems, abnormal gait) may be related, at least in part, to both anatomical and functional abnormalities of the cerebellum. In addition, there also is evidence that cerebellar pathology can bring about a wide range of cognitive and affective deficits (G. Allen & Courchesne, 1998). In fact, one published case study reported on a child who, after surgical resection of a cerebellar tumor, exhibited behaviors after the surgery that were highly characteristic of classic symptoms of Autism, such as gaze aversion, social withdrawal, and stereotyped movements (Riva & Giorgi, 2000).

Although the neuroanatomical and neurofunctional evidence point to a clear association between cerebellar abnormalities and the behavioral manifestation of Autism, the mechanism involved remains unknown. One primary reason is that the general functional properties of the cerebellum in normal brains remain unknown to a large extent. Some preliminary evidence points to anticipatory motor deficits, given increasing evidence that the cerebellum appears to have a role in preparing many neural systems to which it maintains connections (e.g., attention, motor, affect, language) for shifts or alterations in neural responsiveness (G. Allen et al., 2004). G. Allen et al. hypothesize that the cerebellum may accomplish this task by making predictions about what might happen next based on prior learning and may alter responsiveness in the particular neural system(s) needed in upcoming moments. Thus, function in these diverse cognitive realms is not abolished in those with Autism, but lacks in coordination due to a preparatory deficit.

Another strong neuroanatomical finding in individuals with Autism is abnormal developmental changes in overall brain volume. Courchesne and colleagues have shown that brain volume of those children later diagnosed with Autism appeared to be normal at birth (according to neonatal head circumference records), but by age 2 to 4 years, volumetric

MRI data indicated that 90% of the children with Autism had a larger than average brain volume compared to nonautistic children (Courchesne et al., 2001). The observed excessive brain size was due primarily to increased white matter volume in the cerebellum and cerebrum (Courchesne et al., 2001).

Further, a study by Courchesne, Carper, and Akshoomoff (2003) has yielded evidence that there is an increased rate of growth of the brain in infants who later were diagnosed with Autism compared to those who were not, as reflected by measurements of head circumference (HC). Although HC was similar in all infants enrolled in the study during the first few months of life, those who later developed Autism exhibited a marked accelerated rate of increase in HC beginning several months after birth. On average, between birth and 6 to 14 months of age, HC increased from the 25th percentile to the 84th percentile (Courchesne et al., 2003). This increase in HC was associated with greater cerebral and cerebellar volume in these children by 2 to 5 years of age. It is striking that brain size in young children with Autism reaches its maximum by ages 4 to 5 years (Courchesne et al., 2001). Average overall maximum brain size in children with Autism is statistically equivalent to that achieved by healthy children (approximately 1350 mL), but is achieved, on average, 8 years sooner than in normally developing, healthy children (Courchesne et al., 2001). However, in adolescence and adulthood, brain size of those with Autism does not differ from that of nonautistic individuals (Aylward, Minshew, Field, Sparks, & Singh, 2002).

Although the increases in brain volume are marked, the specific underlying cellular components of increased brain volumes are unknown to date. The increased volume found in children with Autism may potentially reflect abnormalities in any number of microstructural features, including excessive numbers of neurons and/or glial cells, excessive dendritic arborization, and/or atypically large numbers of axonal connections (Courchesne et al., 2003). In addition, the cause of the increase in brain volume is not completely understood, but clearly reflects some type of dysregulation in one or more stages of brain developmental processes; however, it appears that the early transient period of brain overgrowth is an important underlying factor in the emergence of many of the behavioral symptoms seen in Autism. The observed overgrowth occurs during an important period of brain development when normative experience-dependent processes of neural plasticity are potentially at a maximum. This extended period of gradual axonal and dendritic growth and synapse refinement and elimination

appears to occur well into the 1st decade of postnatal life. In children with Autism, however, it appears that the physical growth of the brain is compressed into a relatively short period of time, that may in turn result in aberrantly rapid and disordered growth (Courchesne et al., 2003). Such a rapid pace of growth would not allow the normal process of experience-dependent neural plasticity to take place.

Observations of disturbances in normal neurodevelopmental processes in Autism have helped to refine theory and guide research concerning the underlying biological mechanisms of this pervasive developmental disorder. The accumulated (and still growing) knowledge on normal brain development has enabled investigators in Autism to differentiate the abnormal neurodevelopmental processes that appear to underlie this disorder.

Ultimately, it appears that the key etiological feature of Autism is abnormality of the neurodevelopmental process across a wide spectrum of brain regions and networks. The emerging evidence increasingly points to abnormal regulation of brain growth in Autism, with pathological deviation from normative mechanisms underlying the typical progression through neurogenesis and synaptogenesis, followed by axon pruning and synapse elimination.

Despite the wide range of theoretical formulations and the relative paucity of consistent data pointing to a common underlying neurobiological "cause" of Autism, the study of this disorder provides an excellent example of the increasingly important role played by neuroscience in examining the potential biological contributors to a developmental disorder. Examining the evolution of theory and research in Autism also provides very useful information concerning the developmental trajectory of this disorder, and perhaps could provide insight into how the study of the development of the neural substrate underlying this disorder could inform the study of other disorders, as well as normal development. As we noted earlier, one of the fundamental tenets of developmental psychopathology is that the study of the development of disordered outcomes can be informed by an understanding of normal development (Cicchetti, 1984, 1990, 1993, 2003). Ideally, the study of normal and abnormal developmental sequelae can work in tandem to inform each other (Cicchetti, 1984, 1993; Sroufe, 1990). Autism is an excellent example of this principle at work. Also, the advances in our understanding of Autism have come as a result of close collaborations between behavioral and biological scientists working across multiple levels of analysis (Akshoomoff, Pierce, & Courchesne, 2002; Rodier, 2002). The success of such collabora-

tive, cross-disciplinary efforts in the study of Autism, and the wealth of new knowledge that has emerged as a result, serve as an excellent example of the importance of a multi-disciplinary, multiple levels of analysis approach to the study of neurodevelopmental disorders.

A View from Schizophrenia

Congruent with the theoretical principles of a developmental systems approach on brain development, it is expected that a dedifferentiation and disintegration would characterize the neurobiological and psychological development and functioning of individuals with mental disorders. Much of the contemporary research in the area of neurodevelopment and Schizophrenia owes a significant portion of its historical roots to the formulations of Emil Kraepelin (1919), who conceived of Schizophrenia as a deteriorating brain disease in its natural history, albeit with an onset in early adult life. Since the 1980s, when a resurgence of interest in initiating neurobiological studies in Schizophrenia took place, Kraepelin's viewpoint has been challenged and radically altered by advances from several levels of inquiry that point to a prenatal-perinatal origin of at least some of the brain abnormalities found in individuals with Schizophrenia (Cannon, 1998; Keshavan & Hogarty, 1999; Mednick, Cannon, Barr, & Lyon, 1991; Walker & DiForio, 1997; Weinberger, 1987). During the early 1980s, a number of investigations converged and all found evidence for increased ventricle size in persons with schizophrenic illness (Shenton et al., 2001). These enlarged ventricles were present at the onset of the illness and did not protract in size as the illness proceeded over time, even in prospective longitudinal studies. This finding suggested that a neurodegenerative process was not responsible for causing the illness.

The retrospective observations of Laura Bender (1947) and Barbara Fish (1957), as well as the follow-back study by Norman Watt (1972), in which a pattern of abnormalities in neurological and behavioral parameters dating back to childhood were found in adults with Schizophrenia, laid the seeds of the neurodevelopmental hypothesis of Schizophrenia (Marenco & Weinberger, 2000). Moreover, a number of longitudinal studies demonstrated that some degree of recovery was possible in some cases of Schizophrenia (Garnezy, 1970; Tsuang, Wollson, & Fleming, 1979; Zigler & Glick, 1986), thereby casting further doubt on the Kraepelinian viewpoint that Schizophrenia is a degenerative disease of early adulthood ("dementia praecox").

Similarly, prospective longitudinal high-risk offspring studies have revealed that behavioral antecedents of

Schizophrenia occurred before the disease. Fish (1977) demonstrated that a neurobiologic disorder exists in infants and children prior to the onset of more chronic forms of Schizophrenia. Fish's (1977) discovery of pandevelopmental retardation was considered an early marker of the inherited neurointegrative defect (i.e., schizotaxia) postulated to exist in Schizophrenia by Paul Meehl (1962). Importantly, Fish noted that the phenotypic manifestations of the neurointegrative defect change over epigenesis and that the signs of dysregulation of maturation are found in many developing systems. Specifically, Fish reported that the neurointegrative disorder present from infancy disrupted the normal timing, sequence, and overall organization of development. Moreover, in a landmark prospective longitudinal investigation, Fish, Marcus, Hans, Auerbach, and Perdue (1992) discovered that the infant offspring of schizophrenic mothers displayed greater lags in their motor development during infancy and that a number of these infants themselves went on to develop Schizophrenia or schizotypal personality disorders (see also the seminal work of Walker, Davis, & Gottlieb, 1991, in this regard).

Relatedly, Cannon, Rosso, Bearden, Sanchez, and Hadley (1999), in their epidemiological investigation of the Philadelphia cohort of the National Collaborative Perinatal Project, provide compelling evidence that adverse experiences during gestation and birth, as well as deviant cognitive, motor, and behavioral functioning during early childhood, are associated with an increased risk for Schizophrenia. In particular, these investigators demonstrated that the risk for Schizophrenia increases linearly with the severity of fetal oxygen deprivation. In prior neuroimaging studies of high-risk samples (Cannon, Mednick, Parnas, & Schulsinger, 1993; Cannon et al., 2002), a history of perinatal hypoxia was found to be associated with increased severity of a neuropathological indicator of Schizophrenia (i.e., ventricular enlargement) among individuals with an elevated genetic risk for the disorder, but not among controls at low genetic risk. Together, this evidence suggests that a genetic factor in Schizophrenia may render the fetal brain particularly susceptible to the effects of oxygen deprivation and encourages search for molecular mechanisms underlying this heightened neural vulnerability.

Cannon et al. (1999) also discovered that preschizophrenic individuals show evidence of cognitive, motor, and behavioral dysfunction during the first 7 years of life (cf. Walker, Davis, et al., 1991). Because there was not evidence of significant intraindividual decline during this period within any domain of functioning, the results argue against the view that a deteriorative neural process underlies these early phenotypic expressions of liability to

Schizophrenia. Rather, the findings suggest that an increasing number of diverse phenotypic signs emerge with age as the various brain systems required for their expression reach fundamental maturity. Finally, because similar functional disturbances were observed in the unaffected siblings of the preschizophrenic cases, it would appear that these cognitive, motor, and behavioral disturbances are indicators of an inherited neural diathesis to Schizophrenia (cf. Walker & Diforio, 1997).

In addition to the early and more recent work with preschizophrenic infants and children that served as an impetus for modifying the Kraepelinian (1919) view of Schizophrenia, contemporary findings have contributed to the belief that the neurobiological foundations of Schizophrenia are established, at least in part, during the development of the brain. These include the following:

1. A number of prospective longitudinal investigations has discovered an association between prenatal and perinatal complications (e.g., fetal hypoxia) and an increased risk for the later development of Schizophrenia. These findings suggest that the adverse effects of obstetric complications on the developing fetal brain may play a role in the etiology of Schizophrenia.
As Rakic (1988a, 1988b, 1996; Sidman & Rakic, 1982) and Nowakowski (1987; Nowakowski & Hayes, 1999) have concluded, during periods of rapid brain development in which neuronal migration is occurring and synaptic connections are formed the fetal brain is especially vulnerable. Exogenous teratogens, such as maternal influenza (Brown et al., 2004; Mednick, Machon, Huttenen, & Bonett, 1988) and maternal exposure to toxoplasmosis (Brown et al., 2005), along with obstetric complications, such as perinatal hypoxia (Cannon, 1998), in concert with the genetic predisposition to Schizophrenia, may exert dramatic effects on the regions of the brain experiencing the most rapid growth. Introducing birth complications and teratogens may also place the cortical connections being established and refined at increased risk for aberrant development.
2. A number of postmortem neuropathology studies has found evidence of heterotopic displacement of neurons in various regions of the brain, including the hippocampus and the frontal and temporal cortices. These findings suggest that there are disturbances of brain development in utero in many schizophrenics.
3. Disturbances in neurogenesis, neuronal migration and differentiation, synaptogenesis, neuronal and synaptic pruning (perhaps resulting in reduced synaptic connectivity; cf. McGlashan & Hoffman, 2000), and myelina-

tion, occurring at the cellular and molecular levels, suggest that Schizophrenia is a disorder that is instantiated in brain development (Arnold, 1999; Breslin & Weinberger, 1990; Weinberger, 1987).

For example, the laminar distribution of cortical neurons is displaced inward in Schizophrenia, indicating a defect in cortical organization, suggesting that the normal process of “inside-out” neuronal migration (cf. Rakic, 1988a, 1988b) during the second trimester of gestation also is likely to be anomalous, as should the neuronal connectivity and circuitry (Arnold, 1999; Weinberger, 1995). In addition, Lewis, Hashimoto, and Volk (2005) concluded that there are atypicalities in cortical inhibitory neurons (i.e., GABA neurons) in Schizophrenia and that these abnormalities play a role in the impairments of working memory function that are a core feature of clinical Schizophrenia. Moreover, alterations in dopamine and glutamate neurotransmission in the dorso lateral prefrontal cortex (DLPFC) also are involved in the working memory dysfunction in Schizophrenia. Relatedly, Meyer-Lindenberg et al. (2005) have discovered that hippocampal dysfunction may manifest in Schizophrenia because of an inappropriate bidirectional modulatory relation with the DLPFC.

4. A growing body of neuroimaging studies has identified gross structural neuroanatomical changes in young, untreated patients in their first psychotic episode. Further, and in contrast to a Kraepelinian (1919) neurodegenerative viewpoint, these investigations also have failed to discover evidence of deterioration in these neuropathological markers with increasing length of illness (Marenco & Weinberger, 2000).
5. A number of the unaffected first-degree relatives of schizophrenic patients manifest the structural and functional brain abnormalities observed in schizophrenics, implying that such abnormalities may be mediated, in part, by genetic predisposition to the disorder (Cannon et al., 1993; Cannon, Mednick, et al., 1994). Homeobox genes, which serve as transcription factors regulating gene expression, represent potential candidate genes in disorders in which a disruption of cortical neurogenesis has been implicated, such as in Schizophrenia (Ruddle et al., 1994; Steingard & Coyle, 1998).

We wish to underscore that the extant models linking neurodevelopment and Schizophrenia point to a nonlinearity of relations. Specifically, a significant amount of time elapses between the gestational events hypothesized to create a predisposition to Schizophrenia and the onset of the symptoms of the disorder later in life. Longitudinal

follow-up of individuals who have experienced traumatic insults to the brain at early stages of development, such as is likely the case in many instances of Schizophrenia, enables investigators to chart and observe the changing expression of these early lesions as development modifies behavior in general.

Alternatively, for some individuals it also is conceivable that the lesion directly affects later developmental processes via cascade, propagation, and expansion (Cicchetti & Tucker, 1994a; Courchesne et al., 1994; Post et al., 1994; Steingard & Coyle, 1998). These options all provide an opportunity to discover how brain and behavior reorganize following the experience of insults at different points in the developmental course.

Because not all persons who experience the gestational disturbances noted in the literature go on to develop clinical Schizophrenia, Gottlieb's (1992) concept of probabilistic epigenesis is evoked. Furthermore, the existing research reveals that there are a number of pathways through which the early neurodevelopmental anomalies may result in Schizophrenia. The identification of these diverse pathways to Schizophrenia provides insight into how specificity and differentiation into a syndrome may result from a commonality of initiating circumstances (i.e., equifinality; see Cicchetti & Rogosch, 1996). These multiple pathways embrace a number of possible contributors that may potentiate or mediate the links between early neurodevelopmental anomalies and Schizophrenia in genetically vulnerable individuals. These include the normal developmental changes that take place during late adolescence and early adulthood, such as: (1) synaptic pruning of the prefrontal cortex (Feinberg, 1982; McGlashan & Hoffman, 2000), (2) pubertal increases in gonadal hormones during adolescence (Spear, 2000; Walker, Sabuwalla, & Huot, 2004), (3) developmental transformations in prefrontal cortex and limbic brain regions (Dahl, 2004; Keshavan & Hogarty, 1999; Marenco & Weinberger, 2000), (4) continued myelination of intracortical connections (Benes, 1989; Gibson, 1991; Yakovlev & LeCours, 1967), (5) alterations in the balance between mesocortical and mesolimbic dopamine systems (Benes, 1989, 1997; Benes, Turtle, Khan, & Farol, 1994), (6) the stress that arises during postnatal social development (Keshavan & Hogarty, 1999; Walker & Diforio, 1997), (7) the transformations that occur in cognitive and social-cognitive development (Keating, 1990; Noam, Chandler, & LaLonde, 1995; Spear, 2000), and (8) the growing importance of the peer group (J. G. Parker, Rubin, Price, & DeRosier, 1995).

Such an integrative, interdisciplinary approach is necessary to capture the full complexity of schizophrenic illness,

including the multiple pathways to, and the diverse outcomes associated with, the disorder. Thus, it appears likely that the processes underlying the normal development and maturation of cortical circuitry and connectivity may have gone awry in Schizophrenia (Arnold, 1999; Benes, 1995; McGlashan & Hoffman, 2000; Weinberger, 1987). Unraveling these misorganizations in brain development should contribute greatly to understanding the genesis and epigenesis of schizophrenic disorders.

As highlighted in the previous sections, advances in neuroscience have begun to inform neurodevelopmental theories of Autism and Schizophrenia. Other lines of research have begun to examine other forms of psychopathology (e.g., Attention Deficit/Hyperactivity Disorder, Conduct Disorder, Bipolar Disorder) in a neurodevelopmental context (see Cicchetti & Cannon, 1999a; Cicchetti & Walker, 2003). In fact, it is clear that developmental psychopathology has made great strides in recent years to incorporate multiple levels of analysis in its conceptual and empirical framework, and the understanding of the development of psychopathology generally has made great advances by employing findings from basic neuroscience and normal brain development. As previously noted, one of the fundamental tenets of developmental psychopathology is that knowledge of normal development can and should inform the study of deviant developmental trajectories eventuating in psychopathology. One logical extension of this approach is the investigation of the mechanisms and developmental pathways that eventuate in positive outcomes despite the experience of significant adversity. Knowledge from neuroscience and its associated subdisciplines has only recently been brought to bear in preliminary theoretical discussions of a biology of resilience (Charney, 2004; Curtis & Cicchetti, 2003), and, to date, no published empirical studies have incorporated this level of analysis in the investigation of resilience. As part of a complete integration of multiple levels of analysis (including biological) into the developmental psychopathology framework, we believe it is critical to begin to examine the biological contributors to resilient functioning.

RESILIENCE

Positive adaptation in the face of adversity has captured the interest and imagination of humanity over the ages. However, systematic empirical study of the phenomenon that is today referred to as resilience began only a little more than 30 years ago (Cicchetti & Garmezy, 1993; Masten, Best, & Garmezy, 1990). In the early 1970s, a few

researchers investigating the development of psychopathology began to discuss the importance of examining characteristics of children who did not develop psychopathology, despite being at risk (e.g., Anthony, 1974; Garmezy, 1971, 1974), marking an important shift in theoretical depictions of the causes and consequences of psychopathology. Previously, investigations conducted on high-risk and mentally disordered populations across the life span had portrayed the developmental course as deterministic, inevitably resulting in maladaptive and pathological outcomes (Luthar et al., 2000). As researchers discovered that not all high-risk children manifested the dire consequences that extant theories of psychopathology predicted, understanding the processes through which children at risk did not develop psychopathology became viewed as important for informing theories on the development of maladaptation and pathology. The advent of modern neuroscience along with its many associated subdisciplines represents an unprecedented opportunity to augment current conceptual and methodological approaches to the study of resilience (Cowan et al., 2000).

A large volume of research over the past 3 decades has examined the psychosocial correlates of individual, interpersonal, familial, and broader environmental contributors to resilience (Luthar, 2003; Luthar et al., 2000; Masten, 2001). However, the empirical study of resilience, for various historical reasons, has focused exclusively on behavioral and psychosocial correlates of, and contributors to, the phenomenon, and has not examined biological correlates or contributors (Curtis & Cicchetti, 2003; Luthar et al., 2000). Taken as a whole, the extant empirical literature on resilience has traditionally employed behavioral indices of adversity and positive adaptation.

Although this research has yielded a wealth of knowledge concerning the psychosocial correlates of, and contributors to, resilience, early theorizing and research in resilience (e.g., Anthony, 1974; Garmezy, 1974; Murphy, 1974), as well as several subsequent large-scale longitudinal studies of resilience (e.g., Garmezy, Masten, & Tellegen, 1984; Garmezy & Tellegen, 1984; Masten & Garmezy, 1985; Werner & Smith, 1982), were undertaken prior to the inception of modern techniques for examining the neural and biological correlates of human behavior and development. In addition, the scientific study of resilience had its roots in the psychodynamic and behavioral theoretical traditions, where research was largely guided by the study of risk and symptom treatment (Masten & Reed, 2002). Within these conceptual frameworks, which dominated clinical and developmental psychology through much of the twentieth century, there was little interest in discovering the

biological mechanisms that could potentially contribute to a more integrated understanding of behavioral differences (Nelson et al., 2002). Undoubtedly, the relative neglect of the brain and biology as relevant to developmental theorizing on the unfolding of adaptive and maladaptive behavioral outcomes was due, in part, to the paucity of information that existed about the structural and functional organization of the brain (Johnson, 1998; Segalowitz, 1994). There simply was not enough knowledge about brain development and function to articulate its role in the genesis and epigenesis of normal and deviant mental processes. Several cogent and extensive summaries of resilience theory and research have been published that have explicated the need to examine the processes contributing to resilience from multiple levels of analysis, in particular from the level of brain and neurobiological functioning. An important discussion has begun concerning the incorporation of the biological level of analysis into the theoretical framework of resilience (see, e.g., Curtis & Cicchetti, 2003; Luthar et al., 2000; Masten, 2001; Masten & Reed, 2002; Nelson, 1999), and preliminary proposals concerning the empirical examination of the biological foundations of resilience have recently been made (Charney, 2004; Cicchetti, 2003; Curtis & Cicchetti, 2003; Davidson, 2000). At this point in the empirical investigation of resilience, the next logical step is to include a biological perspective on resilience in order to achieve a truly complete understanding of this phenomenon.

Within the scope of this section, it is not possible to cover all of the areas of biological functioning that might potentially contribute to resilient functioning. Rather, we focus on several broad areas that directly and/or indirectly reflect the functioning of major human biological systems that have clear links to human behavior. In particular, we consider the possible contributions of genetics, neuroendocrinology, immunology, emotion, cognition, and neural plasticity to resilient functioning. There is evidence to suggest that the environment and experience may exert an impact on these areas, thus, perhaps, playing a role in resilient functioning. Within each of these areas, we evaluate the pertinent evidence supporting the association of that particular system with resilience and suggest possible research methodologies that could be brought to bear to examine general questions and hypotheses concerning the likely relation between resilience and each area reviewed.

Going forward, it is critically important to keep in mind that biological domains do not function independently, but, more often than not, the functioning of one system influences the functional properties of one or more other systems, through a cascade of bidirectionally influenced processes (Cicchetti & Cannon, 1999a; Gottlieb, 1992;

Gottlieb et al., 1998; Thelen & Smith, 1998). In addition, based on the reality that biological systems function interdependently as much as possible, the goal of future research on resilience and biology should be to increasingly incorporate multiple biological measures as part of a multiple levels of analysis approach to resilience research (Cicchetti & Curtis, *in press*). With this as an ideal, admittedly the challenges involved in a true integration are great. To be complete, such synthesis must involve integration at the highest level across disciplines (i.e., neuroscience and psychology), but also must examine multiple biological systems within the organism (e.g., neuroendocrine and emotion) as well as investigate different levels within the same system (e.g., neuroanatomical and neurochemical). Historically, conceptual distinctions among and within systems have been created (e.g., higher and lower order cognition) in order to more conveniently study the functional details of these systems. However, given the increasing recognition of the importance of considering many levels of interdependent processes simultaneously in order to advance the understanding of a multifaceted phenomenon, such as resilience, it is incumbent upon resilience researchers to meet the challenge of simultaneously incorporating multiple levels both across and within systems.

The discussion in this section of the chapter focuses in part on the conceptual basis for the consideration of biological processes that may potentially yield contributions to expanding our knowledge about resilience. In addition, we discuss various types of neuroimaging and other technologies, such as magnetic resonance imaging (MRI), functional MRI (fMRI), electroencephalography (EEG), event-related potentials (ERPs), assay techniques for neuroendocrine and immune functioning, and methods for investigating gene expression as methodological tools that could be employed to help answer questions about the contribution of biology to resilience. However, the discussion of these tools are secondary to what we believe is the more important general discussion of biology and resilience, as well as the research questions that should be developed to further our understanding of the interface of these two areas.

Theoretical Approach

One of the formidable challenges inherent to examining resilience from a biological perspective is the need to extend current theoretical conceptualizations about resilience in order to incorporate the various new levels of analysis potentially involved in this approach. Most investigators in the area of resilience do not have formal training in neuroscience or biology, whereas those investigators who do

have such training generally have not been involved with research in the area of resilience. Given the vast range of expertise that could ultimately be required to investigate the role of biology in resilience, it is imperative that a multidisciplinary approach to both theory building and empirical investigation is brought to bear on this problem. Indeed, given that self-righting, one of the basic mechanisms underlying resilience, has its historical roots embedded in the fields of embryology and genetics (Fishbein, 1976; Waddington, 1957), we think that it is especially unfortunate that behavioral scientists have thus far eschewed the inclusion of biological measures in their research armamentaria on resilience.

In setting forth a conceptual model of biology and resilience, particular attention must be paid to the relation between the dynamic process of resilience and key components of the central nervous system, neuroendocrine, and other neurobiological systems. An explanatory model of resilience and biology will build and expand upon the extant theoretical framework around resilience, in particular, one that views resilience as a dynamic process that is influenced by neural and psychological self-organization, as well as transactions between the ecological context and the developing organism (Cicchetti & Tucker, 1994a; Egeland, Carlson, & Sroufe, 1993). Specifically, the transactional, organizational perspective (Cicchetti & Schneider-Rosen, 1986; Cicchetti & Sroufe, 1978), one of the major theoretical approaches in the field of developmental psychopathology, provides an orientation that inherently takes into account multiple levels of analysis and allows for combining biological and psychological mechanisms within the same explanatory framework (Cicchetti & Tucker, 1994a), thus providing a ready-made structure for the integration of a biological perspective into resilience. In addition, a transactional, organizational perspective is useful in that it does not ascribe ascendancy to any level of analysis over another, and it attempts to break down the traditional restrictive conceptual boundaries between nature and nurture and biology and psychology (Cicchetti & Cannon, 1999a; Gottlieb, 1992).

As we described earlier in this chapter, advocates of a self-organizing systems-theory viewpoint of neurobiological and psychological development contend that individuals actively participate in the creation of meaning by structuring and restructuring experience through self-regulated mental activity (Cicchetti & Tucker, 1994a; Mascolo, Pollack, & Fischer, 1997). Early experience and prior levels of adaptation neither doom the individual to continued maladaptive functioning nor inoculate the individual from future problems in functioning. Change takes place in a

system as new needs and environmental challenges destabilize the existing organizations, necessitating the emergence of new organizations that may prove to be more adaptive than the preexisting ones in the current context. The reorganizations that occur both within and between developmental domains (e.g., emotion, cognition) provide critical opportunities for resilient adaptation (Cicchetti & Tucker, 1994a).

Furthermore, despite the important role that genetic information plays in regulating, guiding, and controlling brain development (Rakic, 1988a, 1988b, 1995), as we noted earlier, a not insignificant portion of postnatal brain development is thought to occur through interactions and transactions of the individual with the environment (Black et al., 1998; Cicchetti & Cannon, 1999a; Johnson, 1998; O'Leary, 1989). This potential for structural and functional reorganization of the brain in response to environmental demand and afferent input shapes development in the form of a nonlinear, dynamic feedback system (Elbert, Heim, & Rockstroh, 2001). Such development proceeds hand in hand with structural modifications of the brain that can occur on both a microscopic, cellular scale with, for example, alterations in synaptic efficiency, synapse formation, and changes in properties of dendrites, as well as at a macroscopic level with functional reorganization of entire neural networks (Elbert et al., 2001). Consequently, each individual may traverse a potentially unique and partly self-determined developmental pathway of brain building that we believe may have important consequences for the development of resilient adaptation (Black et al., 1998; Cicchetti & Tucker, 1994a). Much of the underlying empirical work in support of this perspective on neural development has been in the area of sensory, language, and perceptual organization and function (e.g., Cheour et al., 1998; Elbert, Pantev, Wienbruch, Rockstroh, & Taub, 1995; Hubel & Wiesel, 1979). However, it is probable that parallel processes shape the development of higher-order, widely distributed cortical functions involved in emotion and cognition that more directly underlie complex, behaviorally manifested phenomena, including resilience.

Avoiding Reductionism

In attempting to integrate a biological perspective into the study of resilience, it is critical to avoid the potential pitfall of reducing the phenomenon of resilience to one that is exclusively mediated by biology. It is possible that the discussion of the biology of resilience could lead to the mistaken conclusion that, if biological mechanisms were associated with resilient outcomes, then the forces of biol-

ogy would be of primary importance in achieving positive outcomes in the context of adversity. However, nothing could be further from the truth.

In fact, reducing psychological phenomena to components of neuroanatomical, neurochemical, neurophysiological, and genetic factors dismisses the great impact that the environment has on these processes, and demotes psychology to the realm of ephemeral behavioral marker of biological processes (see Miller & Keller, 2000). This reductionism is of particular concern in the study of psychopathology, where over the past decade there has been an increasing emphasis on the neurobiology of mental disorders, often attributing (reducing) the etiology of psychopathology to purely innate characteristics of the individual, such as genes, neuroanatomy, or brain function (Charney, Nestler, & Bunney, 1999; Torrey, 1997). More broadly, the artificial distinction between biology and behavior within the human organism contradicts years of research indicating co-actions between all levels of analysis, from the environment broadly construed to the molecular (e.g., Cicchetti & Tucker, 1994a; Gottlieb & Halpern, 2002), and it also highlights the importance of avoiding the perpetuation of the outmoded dichotomy in developmental science between nature and nurture (e.g., Hinde, 1992; Johnston, 1987). Thus, in the context of the current discussion of resilience and biology, we do not wish to convey or encourage the reduction of resilience to biological process. Rather, consistent with a transactional, organizational, general systems theory framework, we believe that biology is but one part of what should be an all-encompassing systems approach to understanding resilience, which needs to take into account all levels of analysis, from molecular to cultural.

Equifinality and Multifinality

Diversity in process and outcome are hallmarks of the developmental psychopathology perspective (Cicchetti, 1990; Cicchetti & Rogosch, 1996; Sroufe, 1989). The existence of equifinality, the recognition that a diversity of paths may eventuate in the same outcome, and multifinality, the acknowledgment that different outcomes are likely to evolve from any original starting point, challenges theorists and researchers to entertain more complex and varied approaches to how they conceptualize and investigate normal development, psychopathology, and resilience (Richters, 1997).

The application of equifinality to a biology of resilience requires that researchers be aware that a variety of developmental progressions may eventuate in disorder or resilience (Luthar et al., 2000). Clearly, biological and psy-

chological factors both can play a role in the pathways to these diverse outcomes. Furthermore, the relative contributions of biological and psychological contributors to disorder and resilience will vary among individuals.

Likewise, the concept of multifinality alerts resilience researchers to the fact that individuals may begin on the same major developmental trajectory and, as a function of their subsequent "choices," exhibit very different patterns of maladaptation or adaptation (Sroufe, 1989; Sroufe, Egeland, & Kreutzer, 1990). The pathway to either psychopathology or resilience is influenced, in part, by a complex matrix of the individual's level of biological and psychological organization, experience, social context, timing of the adverse event(s) and experiences, and the developmental history of the individual.

Technology, Methodology, and Resilience

There is a vast array of rapidly evolving technologies in the biological sciences that can be applied to the study of development and psychopathology, many of which can now potentially play an important role in the study of the interface between biology and resilience. However, an important caveat with respect to these new tools is that the utilization of technology, without an underlying model or theoretical framework, does not serve the advancement of science (see also Peterson, 2003). In the absence of any specific, empirically based knowledge concerning the relation between biological systems and a particular behaviorally manifested psychological phenomenon (e.g., resilience), the initial challenge during the early stages of such research is to, at the very least, generate *a priori*, testable hypotheses that have a reasonable degree of fidelity with a clearly specified conceptual model. Although the construction of an elaborate, formal theory that specifically describes the relation between biology and resilience is overly ambitious at this juncture, it is nonetheless critical to ground empirical endeavors in some framework that is based either on a viable model or some type of functional theory.

In addition, with the continuing advances in and increasing utilization of new technologies in neuroscience and psychology, particularly neuroimaging, it is of paramount importance to avoid having the construction of theory and subsequent generation of hypotheses driven or constrained by the nature of the data that is attainable by a particular measurement technology. Thus, it is important not to exclusively conceptualize a psychological phenomenon, such as resilience, through the lens of a particular methodology. For example, fMRI is an excellent tool for localizing the functional aspects of brain regions and

networks. Thus, application of this method would be ideal for answering questions about where in the brain a particular cognitive or emotional operation is taking place. However, the types of tasks that can be administered to individuals during the fMRI scanning procedure are, by necessity, often limited to those that can be physically adapted to the MRI scanner environment. Thus, the questions that can be answered by functional imaging are to a great degree dependent upon the nature and demands of the task administered, which may often be quite narrow in scope.

Furthermore, although fMRI affords excellent spatial resolution (on the order of a few millimeters), it does not provide good temporal resolution of neural activity (continuing advances in technology have somewhat improved this aspect of the technology, however). Alternatively, ERPs are an example of an ideal brain-imaging technology for detecting the temporal sequence of brain processing (resolution on the order of milliseconds), but unfortunately, the spatial resolution of ERPs is relatively poor (again, this aspect of ERP technology is also improving due to high density electrode arrays and improved source localization algorithms). Thus, the particular characteristics of these two measurement techniques in large part determine what type of data can be derived and, more fundamentally, what types of questions can be asked in research utilizing them. Of course, combining these two methods is an ideal solution for overcoming their individual limitations (e.g., de Haan & Thomas, 2002).

Moreover, as technology in biologically based areas of inquiry becomes increasingly complex and more specialized skills are required to carry out research employing these tools, researchers will naturally become more knowledgeable in the use of one particular methodology and measurement technique (e.g., fMRI). This increasing specialization may have the unintended consequence of narrowing the focus of model building and hypothesis generation. Clearly, no one individual can master all available techniques, thus pointing to the importance of collaboration across disciplines in research examining multiple levels of analysis. Ideally, a comprehensive research program would employ several measures at various levels of analysis, such as molecular genetic, neuroendocrine, functional brain imaging, neuropsychological assessment, and observational ratings of behavior.

EXPERIENCE AND THE BRAIN: A BRIEF HISTORY

From the perspective of modern neuroscience and associated disciplines, it is a given that certain types of experi-

ence result in enduring physiological changes in the brain, by way of a process referred to as neural plasticity. These changes can occur and are observed on one or more levels of analysis, including molecular, cellular, neurochemical, and anatomical brain systems, and are manifested at the highest order by changes in behavior. However, in fairly recent scientific history the fundamental question of whether experience resulted in changes in the physiological characteristics of the brain did not have a clear answer, and was a subject of active empirical inquiry.

In a comprehensive historical review of research on the relationship between experience and the brain, Rosenzweig, Bennett, and Diamond (1972) reported that the earliest recorded scientific account of physical changes in the brain as a result of experience was written in the 1780s by Michele Gaetano Malacarne, an Italian anatomist. He experimented with two dogs from the same litter, as well as pairs of parrots, goldfinches, and blackbirds, each pair from the same clutch of eggs. He trained one member of each pair to perform various tasks (in the case of the dogs) and to make specific vocalizations (the birds). He did not train the other member of the pair. After the experiment ended, he examined the animals' brains, and found that there were more folds in the cerebellum of the animals that had gone through the training procedure. Given that the cerebellum is involved in motor functioning, finding increased complexity in this part of the brain was consistent with the intensive training.

In 1791, the physiologist Samuel Thomas von Soemmering wrote that anatomical measurements might demonstrate the effects of experience on the brain, most likely in reference to the work by Malacarne (Renner & Rosenzweig, 1987). Beyond this single reference to Malacarne's work, there is no indication that any other scientists during this era attempted to follow up on this line of research (Rosenzweig et al., 1972).

In the late nineteenth century, scientists became interested in the relation between intellectual ability and training and brain anatomy in humans. Darwin (1874) wrote:

I have shown that the brains of domestic rabbits are considerably reduced in bulk, in comparison with those of the wild rabbit or hare; and this may be attributed to their having been closely confined during many generations, so that they have exerted their intellect, instincts, senses and voluntary movements but little. (p. 53)

In this passage, Darwin is pointing out not only the hereditary nature of brain size, but also attributes it to the rela-

tive experiential deprivation of domestic rabbits compared to wild rabbits.

In the early part of the twentieth century, a scientist and inventor named Elmer Gates claimed that the results of research he conducted, similar to that of Malacarne, demonstrated support for his hypothesis of “brain building” (Renner & Rosenzweig, 1987). Gates theorized “that every conscious mental operation or experience creates in some part of the brain or nervous system new structural changes of cell and fiber . . . producing the embodiment of more mind” (1909, as cited in Renner & Rosenzweig, 1987). Gates apparently did not publish his research findings in any scientific journals; however, some of his work appeared as a series of articles in a publication called *The Metaphysical Magazine* (Renner & Rosenzweig, 1987).

In addition, Gates did not hesitate to extrapolate his work to humans. He is further quoted as saying: “The applications of these principals to human education is obvious. . . . Under usual circumstances and education, children develop less than ten percent of the cells in their brain areas. By processes of brain building, however, more cells can be put in these otherwise fallow areas, the child thus acquiring a better brain and more power of mind. . . .” (pp. 9–10, as cited in Renner & Rosenzweig, 1987). Although Gates did not quite have the details of the impact of experience on brain development correct, his bold (at the time) statements may yet prove prophetic.

In more mainstream scientific and academic circles, researchers in the last quarter of the nineteenth century failed to show that training resulted in changes in the gross anatomy of the brain. In 1895, Cajal speculated, based on the assumption that the brain does not produce new neurons, that cerebral exercise might lead to the establishment of “new and more extended intercortical connections.” This notion was not to be confirmed until many years later. However, at the end of the nineteenth century, the hypothesis of an intrinsic relationship between brain size and use of the brain or intellectual ability was generally abandoned. In addition, a consensus in the scientific community developed that such anatomical changes could not be detected (if indeed there were any). Hence, scientists of this era generally gave up looking for experientially induced changes in brain anatomy.

In 1949, Donald Hebb published his seminal book, *The Organization of Behavior*, in which he outlined a comprehensive theory of behavior that attempted to integrate the physiology of the nervous system and behavioral psychology (Hebb, 1949). A central tenet of his theory was that experience modifies the brain. A few years before this book was published, Hebb (1947) reported on the first

experiment that systematically compared the problem-solving ability of rats reared in different conditions. He reared two litters of rats in his home as pets. They were frequently out of their cages and had free run of Hebb’s house (Hebb, 1949). At maturity, these home-raised rats scored better than laboratory-reared rats on the Hebb-Williams maze (Hebb & Williams, 1946). Hebb concluded that “*the richer experience of the pet group during development made them better able to profit by new experiences at maturity*—one of the characteristics of the ‘intelligent’ human being” (Hebb, 1949, p. 299, italics in the original). Subsequent replications of Hebb’s research under more controlled experimental conditions resulted in similar findings (e.g., Hymovitch, 1952).

However, none of the investigators in this subsequent set of experiments discussed any role that differential brain development may have played in the behavioral results obtained. However, the thinking of these scientists was no doubt influenced by the prevailing dogma of the first half of the twentieth century concerning brain development, which held that the anatomy and physiology of the brain was fixed by a genetic blueprint. It was believed that development proceeded according to this fixed plan until adulthood, after which change in the brain was not possible, except in the case of injury and/or decay from the aging process (Renner & Rosenzweig, 1987). However, during the 1950s, some neuroscientists began to speculate that subtle aspects of the brain may be impacted by experience, such as connections between neurons and neurochemistry (Bennett, Diamond, Krech, & Rosenzweig, 1964). Unfortunately, at this time, scientific methods did not exist that would reliably allow detection of these types of brain processes, and the question reverted to a more speculative realm.

During the early 1960s, a group of scientists at the University of California, Berkeley, began to examine the relation between neurochemical changes in the brain and learning in rats. The results of a series of their early experiments confirmed their specific hypothesis of a linkage between increased cortical activity of the neurotransmitter acetylcholine (ACh), greater efficiency of synaptic transmission, and successful problem solving in rats (e.g., Krech, Rosenzweig, & Bennett, 1960). Indeed, rats who were good at learning mazes had higher ACh activity than those who were not, and it was later found that stimulation and training did, in fact, increase levels of ACh (e.g., Bennett et al., 1964). This early work led to a now classic line of research comparing the brains of rats reared in complex environments to those reared in standard laboratory conditions.

NEURAL PLASTICITY

A recent search of literature databases in medicine and psychology by the authors yielded nearly 10,000 citations that used the term “neural plasticity” as a key word or phrase, with a seemingly exponential increase in the number of publications over the past 5 to 10 years. It would be a daunting task to synthesize the knowledge that has accumulated about neural plasticity generally, and in particular to attempt to apply this knowledge systematically in order to gain a clearer understanding of a behavioral phenomenon, such as resilience. Nearly all of the work on neural plasticity is highly technical, conveyed within specialized reports concerning the mechanisms of neural plasticity at nearly all levels of analysis, including neurochemical, molecular, genetic, and neuroanatomical, intended for a highly trained audience of neuroscientists and biologists (among others). Being able to glean something about the relevance of neural plasticity for resilience (or for that matter, any behavioral phenomenon) from such a highly technical literature is a formidable undertaking.

The study of neural plasticity in modern neuroscience and associated disciplines has brought to bear a wide range of empirical methodologies to describe all aspects of the observed dynamic processes at the synaptic and cellular levels that appear to underly neural plasticity. Neural plasticity is increasingly viewed as a dynamic nervous system process that orchestrates nearly constant neurochemical, functional, and structural CNS alterations in response to experience. It is possible that advances in the study of neural plasticity could be fruitfully employed as a model to begin to hypothesize about the biological underpinnings of resilience. Several authors recently have alluded to the possible relation between the principles of neural plasticity and resilience (e.g., Cicchetti, 2003; Curtis & Cicchetti, 2003; Davidson, 2000; Masten, 2001; Nelson, 1999), and at the conceptual level, there are several intriguing parallels between processes involved with neural plasticity and resilience. Thus, it is important to examine resilience in the context of this vast body of knowledge on neural plasticity, and to evaluate whether neural plasticity may have relevance for the study of a biology of resilience. The following sections attempt to provide a broad conceptual overview of neural plasticity, and briefly examine some of the fundamental mechanisms underlying this inherent characteristic of the brain and how it may potentially inform the study of resilience.

Plasticity: General Definition

Webster’s dictionary (1979) defines plasticity as “the capacity for being molded or altered.” The term plasticity is

employed in a variety of fields in modern science, and until fairly recently has primarily been applied in engineering and physics to index the ability of material to change characteristics depending on environmental and thermodynamic conditions. In its purest semantic sense, plasticity simply connotes the capacity of something (e.g., a material, an organism) to change, and does not take into account the context (i.e., precipitating event[s]) in which this change may come about. In practical usage, however, it is assumed that such change takes place as a result or consequence of an event or context in the environment (e.g., expansion of a material due to increased temperature).

Plasticity can also be used to describe change in the sense of “recovery,” in that the degree to which a material or system is plastic modulates the degree to which that material or system can return to its “original” condition prior to some event that leads to its modification (e.g., brain injury). However, the processes described by plasticity would imply that, regardless of the degree of recovery back to an original structural or functional state, no material (or organism) can ever return to an exact copy or duplicate of a previous condition once that initial condition has been altered. For example, a steel beam expands and contracts without structural disruption within a specified range of temperature. However, if the temperature goes beyond this range (e.g., if it becomes too hot) then the beam changes (melts), but is not able to return to its original shape after the temperature returns to normal. Analogously, the human brain is able to recover from some injuries through self-repairing mechanisms in the central nervous system. However, if the structural integrity of the physical substrate is disrupted to a great degree (e.g., a significant part of the frontal cortex is destroyed via head injury), then the organism may survive but is permanently changed, as the brain’s restorative mechanisms are not able to cope with the degree of change. However, unlike the steel beam whose molecular structure may remain unchanged in the context of the expected range of expansion and contraction due to thermal changes in the environment, an organism may exhibit some degree of functional and/or behavioral recovery from brain injury, but there inevitably are differences in underlying cellular and neuroanatomical structure.

Neural Plasticity: Fundamental Concepts from Neuroscience

Plasticity is of particular interest in the field of neuroscience, and is considered to be one of the fundamental functional mechanisms of the central nervous system. In modern neuroscience, the term neural plasticity generally refers to modification of the component neural substrate of

the brain and other central nervous system structures as a result of some change in conditions (generically referred to as experience), with the assumption that such modification is adaptive for the continued survival and optimal functioning of the organism. Several decades of empirical investigation have revealed that plasticity is an inherent property of the central nervous system, and that the manifestation of plasticity is part of a normative process in the mammalian central nervous system (e.g., Kempermann, van Praag, & Gage, 2000). Indeed, it has been suggested that the plasticity of the human brain, which is broadly reflected behaviorally by learning and adaptation, is one of the central defining mechanisms of the evolutionary success of the human species (Hyman & Nestler, 1993).

There is evidence that all levels of the central nervous system exhibit some form of plasticity, typically in a “bottom-up” fashion, with changes at lower levels supporting (and precipitating) changes at higher levels of the central nervous system. Many, if not all, of the lower-level changes in neural functioning are believed to underlie changes in higher-level neural processes as well as neuroanatomical structure that, in turn, are reflected in changes at higher levels of analysis (e.g., neural networks, learning, memory), producing both short-term and long-term changes. The manifestation of such changes in the neural substrate takes place at varying timescales, from milliseconds to years (Destexhe & Marder, 2004). Within neuroscience, it is clear that the term neural plasticity is used to refer to a multiplicity of processes occurring at many levels of analysis. In addition, the study of neural plasticity must include identifying not only what changes are to be classified as neural plasticity (i.e., what constitutes neural plasticity), but also the mechanisms by which these changes take place (i.e., how does neural plasticity occur), as well as the adaptive, functional, and behavioral outcomes of these changes (what are the consequences of neural plasticity) across multiple levels of analysis. Of course, in many instances the changes that constitute plasticity and the mechanisms by which these changes take place must be described in tandem in order to characterize the broad process referred to as neural plasticity.

It also is important to consider neural plasticity broadly in terms of a nonlinear dynamic feedback system, one that constantly reshapes and reorganizes the organism. Previous neuroplastic changes inevitably influence the form of, and processes underlying, changes that might take place in the future (e.g., Elbert et al., 2001; Johnson, 1999). Neural plasticity takes place as a result of some event (or experience) impinging upon the organism that precipitates a change in the central nervous system. After the change in the system has taken place, the organism is essentially “dif-

ferent,” and the manifestations of this change are represented at multiple levels (although at varying time scales), including behavior (e.g., memory or learning). Finally, such changes can potentially bring about further instances of neural plasticity.

Neural plasticity is not only a property of the developing brain but of the adult brain as well, although the central nervous system is more likely to undergo changes during early development and within certain sensitive periods of development. Moreover, neural plasticity must be thought of in the context of the overall developmental time course of an organism, with neural plasticity being more or less likely to occur at different time points along an organism’s developmental trajectory (e.g., during sensitive periods—see Cicchetti & Tucker, 1994a, 1994b).

In sum, neural plasticity is a multidimensional, highly dynamic process that is strongly consistent with the principles of self-organization of the brain. The primary dimensions of neural plasticity that need to be considered are temporal (i.e., potential developmental constraints as well as time course of neural change), level of action (i.e., cellular, genetic, neural network), precursors (i.e., precipitating event, such as enriched experience, injury), and finally, the resultant change in terms of modified neural structure function and/or observable behavior (see Figure 1.1).

Such a broad systems approach to the understanding of neural plasticity points to the necessity of a multidisciplinary approach to the potential translation of a vast body of information concerning the biochemistry of neural plasticity to the level of observable behavior. The following sections provide a brief overview of some of the types of neural plasticity, and some of the mechanisms underlying them, and begin to identify potential candidate processes that might inform the study of a biology of resilience.

Forms of Neural Plasticity: What Changes

Generally, neural plasticity has predominantly been thought of as reorganization within systems or subsystems of the central nervous system, evidenced by changes in anatomy, neurochemistry, or metabolism, and is most typically studied in the context of several types of events impinging on the central nervous system. Such measures may include physical damage to neural structures, sensory deprivation, normal development of the organism, and a variety of environmental inputs generally referred to as experience (Bavelier & Neville, 2002; Nelson, 2000b). The neuroplastic changes that take place are often dramatic, and can include observable changes in the neural substrate that are translated into changes observable at the behavioral level. Such changes that are the hallmarks of

Figure 1.1 A general schematic of neural plasticity.

plasticity can occur on one or more levels of analysis, including molecular, cellular, neurochemical, neuroanatomical, and at the level of brain systems (Nelson, 1999).

Neuroplastic changes can be manifested in a number of ways, including: the characteristic behavior of single ion channels; the generation of new neural circuitry; dendritic outgrowth and the formation of synapses; the strengthening and weakening of some neural circuits through the processes of synaptogenesis and synaptic removal, respectively; and the sprouting of new axons, or elaborating their dendritic surfaces (Kolb & Gibb, 2001). Advances in the development of sophisticated molecular technologies and sensitive brain-imaging methods have enabled scientists to enhance their comprehension of the functional importance of dendritic spine heterogeneity (Segal, 2005). Empirical evidence suggests that dendritic spines may undergo complex alterations in both shape and number over time following exposure to novel experiences (Segal, 2005), thereby relating these spines to neuronal plasticity and long-term memory formation. Finally, these changes often are exhibited through observable behavioral changes. The following sections briefly summarize a sampling of different types of neural plasticity across several levels of analysis.

Short-term synaptic plasticity involves changes in synaptic activity that occur depending upon the frequency of stimulation and the history of prior activity (Schwarz, 2003). This type of plasticity allows synaptic strength to be modulated as a function of previous activity and can result in large changes in responses during physiologically relevant patterns of stimulation. Hebb (1949) originally suggested that synaptic contacts are modified as a consequence of simultaneous activation of the pre- and post-synaptic neuron (hence, the oft-cited phrase from Hebb, “cells that fire together wire together”). Long-term potentiation (LTP) and long-term depression (LTD) are forms of use-dependent plasticity at the synaptic level that have been the focus of a great deal of inquiry because of their likely correlation with some forms of learning and memory.

Synapses may show declines in transmission or increases in synaptic efficiency over time courses ranging from seconds to minutes to hours (in the case of LTP). These short- and long-term modulatory effects that neurotransmitters exert on their target neurons by way of changes in synaptic activity can be viewed as the fundamental basis of neural plasticity (Nestler & Duman, 2002), and serve as the foundation of higher levels of change within the central nervous system. For example, it is cur-

rently believed that LTP may be a key metabolic mechanism for memory formation (e.g., Chen & Tonegawa, 1997; Malenka & Nicoll, 1999), and it has been further suggested that LTP and LTD are fundamental in the process of behavior change based on experience (Post & Weiss, 1997). Other forms of synaptic plasticity also have been examined as well. For example, synaptic scaling has been examined as a general form of use-dependent regulation of synaptic transmission (e.g., Turrigiano, Leslie, Desai, Rutherford, & Nelson, 1998).

Further elaboration on neural plasticity at the cellular level is beyond the scope of this chapter. Although far removed from behavior, it is important to recognize that these molecular and cellular processes are the very building blocks that form the scaffold for neural plasticity that eventuates in changes in neuroanatomy and neural networks that are then manifested at the level of observable behavior.

Recent work has demonstrated neural plasticity in a wide range of neuroanatomical structures in the cortex. One example of this is reorganization that occurs in the motor cortex, with changes in the motor homunculus (the nonlinear map of the body across the motor cortex) observed as a consequence of the acquisition of motor skills (Steven & Blakemore, 2004). In addition, extensive training of specific limb movements in mammals leads to observable reorganization of the neural substrate of the motor cortex (e.g., Karni et al., 1995; Pascual-Leone et al., 1995).

The somatosensory cortex also has shown evidence of reorganization of representational zones as a result of somatic stimulation. In a well-established line of inquiry with musicians, Elbert and colleagues (e.g., Elbert et al., 1995; Pantev, Engelien, Candia, & Elbert, 2001) have shown enlargement in those areas of the somatosensory cortex of musicians devoted to the particular fingers used to play their instrument. Similarly, the cortical representation of the reading finger in blind Braille readers is increased compared to that of their nonreading fingers and compared to the fingers of sighted and blind non-Braille readers (Pascual-Leone & Torres, 1993). Also, there is evidence that extensive perceptual learning (experience) contributed to the correction of vision deficits in children who previously experienced visual deprivation (Grigorieva, 1996).

Other research has demonstrated neural plasticity in the form of local remapping in the primary visual cortex (V1) in animals in response to discrete retinal lesions. Most knowledge concerning alterations of the visual cortex in humans as a result of experience comes from studies of individuals deprived of sight. There is a large body of evidence indicating that the visual cortex in persons without sight is responsive to tactile and perhaps auditory stimula-

tion (e.g., Sadato et al., 1996). Neuroimaging studies have enabled the direct observation of neural plasticity in humans, and new findings continue to be published at an increasing rate demonstrating structural and functional neural plasticity of many areas of the human brain. For example, a recent structural MRI study showed that learning a second language increased the density of grey matter in the left inferior parietal cortex, with the degree of increase modulated by not only the degree of proficiency attained in the language, but also the age of acquisition (Mechelli et al., 2004).

Neural Plasticity Associated with Environmental Enrichment

Nearly all of the classic and ongoing studies of neural plasticity in animals and humans involve neuroplastic changes that impact the structure and function of primary sensory processes. Much less is known about the influence of experience on cognitive abilities, intellectual functioning, or affective and social development. A vast body of studies from the animal literature point to the direct impact of enriched rearing (relative to standard laboratory cages) on the brain and behavior of several animal species, most typically in rats. The enriched conditions (EC) for rats typically involve being housed in larger-than-standard cages, with a small maze and an assortment of toys inside, whereas control rats are reared in cages by themselves and do not have any contact with other rats. This extensive literature has indicated that being reared in enriched conditions is associated with changes in laboratory animals in neurochemical, physiological, neuroanatomical, and behavioral systems, and has revealed not only changes in the neural substrate of rats but also in their behavior.

Early studies examined changes in neurotransmitter systems in rats in response to rearing in enriched conditions, and these studies consistently demonstrated that the total activity of ACh and ChE was significantly greater in the cortex of the EC raised rats than in control rats reared in isolation, with the greatest increase in the visual cortex (e.g., Bennett et al., 1964; Krech, Rosenzweig, & Bennett, 1962). In addition, rats reared in enriched conditions were shown to have a 6% greater RNA to DNA ratio, suggesting an overall higher metabolic activity in the brains of rats reared in enriched conditions (Bennett, 1976), and there is evidence to suggest that rearing in complex environments enhances the efficiency of molecular transport through axons (Grouse, Schrier, Bennett, Rosenzweig, & Nelson, 1978). In addition, electrophysiological studies have demonstrated that rats reared in enriched conditions

modify their behavior more quickly in response to environmental feedback (e.g., Leah, Allardyce, & Cummins, 1985), and other evidence points to decreased nervous system excitability in EC rats (Juraska, Greenough, & Conlee, 1983).

Numerous studies have demonstrated that the most obvious gross anatomical difference between EC reared rats and those raised in isolation is in total weight of the cortex. Replicated over 16 successive experiments, Rosenzweig et al. (1972) reported that the total cortical weight of EC rats was on average 5% greater than that of control rats, with an average 7.6% increase in the occipital (visual) cortex, 4% in the ventral cortex (which includes the hippocampus), and a 3% increase in the somatosensory cortex. These changes also were found in rats blinded before being placed in the enriched condition, or even when the differential rearing took place in total darkness (Rosenzweig et al., 1969). It thus appears that the brain effects seen in enriched rats are due to multisensory stimulation from the enriched environment, and is not restricted to the visual modality. The observed increase in cortical weight has generally been attributed to, among other factors, a 20% to 30% increase in the number of glial cells in the brains of EC rats (Diamond et al., 1966). EC rats also exhibit thicker cortical regions, with an average increase in thickness of 5% overall (Diamond, Krech, & Rosenzweig, 1964), as well as consistently larger neuronal cell bodies and nuclei than control rats (Diamond, Linder, & Raymond, 1967).

Although a 5% increase in the weight of the cortex may not seem particularly large in an absolute sense, changes of this magnitude in such a central component of the central nervous system can, and do, result in large behavioral changes. For example, destruction of less than 5% of the tissue in the rat occipital cortex can result in a functionally blind animal (Renner & Rosenzweig, 1987), and small lesions in the cortex caused by stroke or injury in humans can result in behavioral changes of great magnitude, such as aphasia or other disorders.

Over the past 30 years, Greenough and his colleagues have addressed how environmental complexity exerts an impact on the actual organization of the brain. Initial work from this laboratory demonstrated that rats reared in complex environments consistently had more high order dendritic branches and more dendritic synapses per neuron in several occipital cortical cell types and the temporal cortex, but not in the frontal cortex (e.g., Greenough, Volkmar, & Juraska, 1973). Environmental enrichment also appears to actively induce synapse formation (Greenough, Hwang, & Gorman, 1985). In addition, rats reared in enriched environments have increased relative density of dendritic spines, more synapses per neuron, and more multiple synap-

tic boutons (Jones, Klintsova, Kilman, Sirevaag, & Greenough, 1997; Turner & Greenough, 1985). Other features indicative of greater synaptic efficiency, such as larger synaptic contacts, also have been found in EC rats (e.g., Turner & Greenough, 1985).

Neuroanatomical changes as a result of enriched rearing conditions also have been found in brain regions outside the cortex. For example, Floeter and Greenough (1979) have demonstrated structural plasticity of Purkinje cell bodies, critical in coordination of movement, in the cerebellum of the Japanese macaque as a function of rearing in differential environments. Somewhat more recently, EC rats have been shown to undergo broad structural modifications of the cerebellar cortex as a result of complex motor skill learning (e.g., Kleim et al., 1998).

Given the importance of the role the hippocampus plays in memory, the influence of differential rearing experiences on this brain structure would be of particular interest. Rats reared in enriched environments have been reported to have more granule cells in the dentate gyrus, a structure adjacent to the hippocampus and a key component of the hippocampal memory circuit, as well as increases in dendritic branching and overall size of the dendritic field (e.g., Susser & Wallace, 1982). Mice reared in enriched conditions showed an overall 15% increase in the depth and number of neurons in the hippocampus (Kempermann, Kuhn, & Gage, 1997).

Behavioral Effects of Enrichment

The most consistent finding across studies is that of superior performance of EC animals in complex problem solving. For example, rats reared in enriched environments show advantages on tasks involving reversal of previously learned visual discrimination (Krech et al., 1962) and other tasks requiring response flexibility (M. J. Morgan, 1973), and are superior at response inhibition in a bar pressing task (Ough, Beatty, & Khalili, 1972) and passive avoidance tasks (e.g., Lore, 1969).

Many studies of learning in rats reared in differential environments have involved spatial problem-solving tasks with various types of mazes, demonstrating improved learning in EC rats (e.g., Brown, 1968) and mice (Kempermann et al., 1997). This superior maze performance appears to be long lasting, even with a 300 day delay period between being taken out of the complex environment and the beginning of the testing period (Denenberg, Woodcock, & Rosenberg, 1968). Others have demonstrated that pregnant rats housed in enriched conditions had offspring who performed better on a Hebb-Williams maze than offspring

of mothers housed in isolated and control environments while pregnant (Kiyono, Seo, Shibagaki, & Inouye, 1985). EC rats also demonstrate more organized and complex bouts of interactions with objects than control rats, perhaps reflecting a higher level of exploratory behavior (Smith, 1972). In addition, mice reared in enriched conditions were less fearful, and exhibited lower levels of both state and trait anxiety (Chapillon, Manneche, Belzung, & Caston, 1999).

Although there are no direct human analogs to animal studies of rearing in enriched versus impoverished conditions (of course, such studies would be unethical), some nearly analogous nonexperimental paradigms involving human enrichment do exist. Programs, such as Head Start, and more recently the Abecedarian Project, have attempted to improve cognitive development and social competence in high-risk young children (e.g., Ramey & Ramey, 1998; Zigler & Valentine, 1979). The Abecedarian Project was designed as a research and intervention study, in order to test whether mental retardation correlated with inadequate environments could be prevented by providing intensive, high-quality preschool programs beginning shortly after birth and continuing at least until children entered kindergarten (Ramey & Ramey, 1992).

Generally, outcome studies of Head Start and other similar programs have shown initial IQ gains followed by subsequent declines, but with positive impact on general school and social competence (Lazar, Darlington, Murray, Royce, & Snipper, 1982). Those who participated in the Abecedarian Project, aside from a small overall advantage in IQ (approximately 5 points overall compared to children not enrolled in the Abecedarian Project), at age 12 and at age 15 also scored significantly higher on a variety of achievement tests, with the intervention group exhibiting a 50% reduction in the rate of failing a grade during elementary school (Campbell & Ramey, 1995). This project in particular has provided evidence that those children who began the program with greater risk benefited the most (Martin, Ramey, & Ramey, 1990). For example, children whose mothers had IQs less than 70 had IQs, on average, 21 points higher than the control children at 4½ years of age. This is in contrast to the mean gain of approximately 8 IQ points for the intervention sample as a whole.

In addition to the measured behavioral and intellectual advantages found in those children who participate in early enrichment interventions, one study has reported the impact of an early human enrichment program on the island of Mauritius on psychophysiological measure of arousal and orienting (Raine et al., 2001). At age 11 years, children who were randomly assigned to an enriched nursery school

intervention at ages 3 to 5 years showed greater skin conductance amplitude, faster rise times and recovery, both at rest and during a continuous performance task, compared to children who received a normal preschool educational experience. In addition, children who had experienced the enriched preschool program showed less slow-wave EEG activity both at rest and during a continuous performance task. These findings suggest both better information processing as well as a greater degree of cortical maturation in the children who participated in the early enrichment intervention (Raine et al., 2001). The results of this study are striking in that they demonstrate a strong association between early enriched preschool experience in humans and later direct measures of brain and psychophysiological functioning.

In a longitudinal follow-up of this sample, the children who participated in the environmental enrichment program at ages 3 to 5 years had lower scores on self-report measures of schizotypal personality and antisocial behavior at age 17 years, as well as showed lower rates of self-reported criminal offenses at age 23 years, compared to those who did not participate in the enrichment program (Raine, Mellingen, Liu, Venables, & Mednick, 2003). These effects were most pronounced in those children who showed signs of malnutrition at age 3 years.

Mechanisms of Neural Plasticity: How Does This Change Take Place?

The mechanism of experience-based neural plasticity begins with the organism interfacing with its environment. Experience “enters” the brain by way of afferent inputs through the sensory modalities. These signals are then relayed via established neural networks to higher cortical areas where a myriad of processes ensure proper disposition of these inputs. There are many hypothesized mechanisms to account for neural plasticity at all levels of analysis, with discrete regulatory mechanisms that occur at each level of neuroplastic change. It also appears that mechanisms governing higher levels of neural plasticity (e.g., changes in representational maps in somatosensory cortex) build upon fundamental processes at the cellular and molecular levels.

The fundamental processes underlying neural plasticity at all levels are believed to be two mechanisms underlying the modulatory effects of neurotransmitters. One of these is protein phosphorylation and the other is the regulation of gene expression (Hyman & Nestler, 1993). It would appear that protein phosphorylation is the major molecular mechanism of neural plasticity, and is generally the mechanism by which the modulation of

neuronal function is achieved, through alterations in the functional state of many different types of neuronal proteins, such as ion channels, neurotransmitter receptors, and processes by which neurotransmitter storage and release is regulated (Hyman & Nestler, 1993). Protein phosphorylation regulates both presynaptic and postsynaptic neurotransmitter receptors, with corroborative evidence suggesting that phosphorylation alters the functional activity of receptors (Hyman & Nestler, 1993). In addition, protein phosphorylation plays a central role in cell growth, differentiation, and movement.

The second primary mechanism by which neurotransmitters can effect long-term changes on the function of target neurons is by regulating gene expression within those neurons. Such changes in gene expression appear to produce quantitative as well as qualitative changes in the protein components of neurons, including, for example, alterations in the numbers and types of ion channels and receptors present on the cell membrane as well as levels of proteins that regulate the morphology of neurons and the numbers of synaptic connections they form (Hyman & Nestler, 1993). Further, neurotransmitters continually regulate neuronal gene expression as a way to fine-tune the functional state of neurons in response to many varied synaptic inputs (Hyman & Nestler, 1993). Regulation of neural gene expression by neurotransmitters can, in some cases, produce quite long-lasting changes in virtually all aspects of neuronal functioning.

Within the brain, gene expression can be activated by both normative and nonnormative (i.e., drugs) physiological processes and experience. Such endogenous or exogenous processes initiate a cascade of events, beginning with incoming afferent sensory information, activate increasingly higher-level neural networks in the brain, eventually resulting in activation of neurons and networks involved with higher-order processing (e.g., language, cognition). In turn, within each of the cells involved in this process, the generation of action potentials as well as the activation of second messenger systems alters the rate of expression of specific genes and, as a result, the expression of multiple types of neuronal proteins (Hyman & Nestler, 1993). The altered levels of these proteins produce changes in processing of subsequent synaptic information by these neurons, thus leading to further changes in the processing of sensory input. It is believed that such mechanisms account for many of the longer-term consequences of experience on brain functioning. Such a regulatory process, whereby activity in one neuron regulates gene expression in another neuron, is referred to as transsynaptic regulation of gene expression, and a class of proteins termed transcription factors (e.g., c-Fos, Zif268) plays a central role in the regulation of neural gene expression (Hyman & Nestler, 1993).

Generally, changes to the central nervous system mediated by protein phosphorylation do not involve changes in protein synthesis and, therefore, are likely to have a rapid onset, be more readily reversible, and have a shorter duration compared to neural plasticity mediated by gene expression. However, both of these processes serve to mediate the long-term effects of experience on the brain. The biochemical and molecular changes brought about through these two processes, through a cascade of intermediate neural processes, lead to changes in the function and efficacy of synapses, changes in the processing of information by individual neurons, and ultimately to changes in the way multicellular neural networks within the brain communicate with each other (Hyman & Nestler, 1993). Protein phosphorylation and gene expression are in some ways considered to represent a form of molecular memory within individual neurons. Likewise, learning and memory at the level of the whole brain are mediated by accumulations of complex combinations of the fundamental types of changes in the function and efficacy of synapses brought about by these two basic processes.

The challenge of future research attempting to relate neural plasticity to particular behavioral phenomena is to find associations between specific alterations in neural processes, brought about by phosphorylation and gene expression and behavior. This challenge is great, given the probable high degree of complexity of linkages between such distal processes, separated by multiple levels of analysis. Greenough, Black, Klintsova, Bates, and Weiler (1999) have proposed an integrative perspective on neural plasticity that may be a starting point for building a framework that enables the large gap between molecular and genetic processes involved with neural plasticity and the expression of behavior to be bridged. They advocate moving beyond a focus on synapses to a consideration of the process of neural plasticity occurring in surrounding tissue elements, cooperative regional neural networks, and diffuse endocrine modulatory effects. As increased understanding of the cellular mechanisms of neural plasticity accumulates, this new knowledge may prove to be fruitful for comprehending some of the molecular processes contributing to resilient functioning. To fully reap these potential benefits of such understanding, it is important that multidisciplinary collaborations take place between neuroscientists and developmental psychopathologists.

Connecting Neural Plasticity and Behavior

Greenough et al. (1993) have stressed that a necessary condition for the behavioral and brain effects of enrichment to be manifested in rats is direct physical interaction with the environment. Animals reared inside an enriched environment but kept in cages to prevent them from physically in-

teracting with the environment do not show the brain or behavioral effects of their littermates who are allowed to physically interact with the enriched environment (Ferchmin, Bennett, & Rosenzweig, 1975). There is also evidence that direct physical interaction with the environment may be important for human development, as exemplified by the work of Bertenthal, Campos, and Barrett (1984), suggesting that interaction with the environment produced by self-locomotion may be an important component of cognitive and emotional development in early childhood.

Together, these motor and sensory processes facilitate learning. How learning-related neuronal activity becomes translated into changes in the structure of neurons, and the mechanisms by which environmental experience becomes translated into structural modifications of neuronal connections, is not yet completely understood (Torasdotter, Metsis, Henriksson, Winblad, & Mohammed, 1998). It appears that the general mechanism responsible for this phenomenon is gene expression, which is one of the fundamental ways that cells adjust to changes and demands placed upon them (Greenough et al., 1993). This process involves the activation of genes in the nucleus of the cell, whereby messenger RNA (mRNA) is transcribed from the genes and codes for the proteins necessary for the formation of new synapses and dendrites. Several studies have begun to show a direct link between gene expression processes and the structural changes resulting from learning (e.g., Alcantra, Saks, & Greenough, 1991).

The second stage in the process of the impact of experience on the brain is in the output, or how these neuronal changes are translated into observed changes in behavior. If neurons have more synapses, then there is more opportunity for these synapses to form or participate in networks, leading to quicker and more efficient processing. This would in turn manifest itself in observable behavior. For example, the behavioral attributes that would correlate with greater levels of neuronal connectivity are most likely the hallmark characteristics of increased flexibility in problem solving seen in rats exposed to complex environments. Finally, it is important to note that the cycle of modification of an organism in an enriched environment builds upon itself in the form of a feedback loop from the second phase to the first, with subsequent change building upon change resulting from previous experiences with the environment.

Applications of Neural Plasticity to Resilience

Although the processes and mechanisms underlying neural plasticity are beginning to be fairly well understood, the difficult challenge faced by theorists and researchers in re-

silience is to devise a model whereby mechanisms of plasticity at the neural level could be linked to the behavioral manifestation of resilience in humans. However, it is important to explicitly examine whether the principles or processes of neural plasticity can contribute to our understanding of resilience. Although understanding the process and manifestation of neural plasticity may serve as a useful heuristic in the investigation of the biological correlates of, and contributors to, resilience, neural plasticity, per se, may not serve as the ultimate explanatory biological mechanism underlying resilience. Therefore, the primary question to be addressed in the following sections is how principles of neural plasticity might inform theory and research on resilience.

Neural Plasticity and Resilience: Some Potential Linkages

A multitude of studies have consistently demonstrated the brain's ability to recover varying degrees of functioning after lesions and other injuries to its physical structure (for review, see Kolb & Gibb, 2001). Kolb and Gibb outline three ways in which the brain could manifest neuroplastic changes in response to injury. In one scenario, there could be reorganization of the remaining, intact neural substrate, most likely involving the generation of new synapses in pre-existing neural pathways. Alternatively, there could be development of entirely new neural circuitry. Finally, new neurons and supporting glia might be generated to replace some of these structures lost in the injury. It is important to consider that all of these regenerative processes most likely occur in tandem with one another, although the exact combination of processes utilized by the brain may vary depending on the developmental age of the organism at the time of injury (Kolb & Gibb, 2001). Finally, each of these neuroplastic processes may also be influenced by other factors, such as experience (i.e., training), neuromodulators, and hormones (Kolb & Gibb, 2001).

Analogous to neural plasticity that takes place in response to brain injury, resilience can be viewed as the ability of an individual to recover after exposure to trauma or adversity (Cicchetti & Rogosch, 1997; Masten et al., 1990). In this view, adversity is thought to exert a damaging effect on one or more neural substrates, and mechanisms of neural plasticity bring about recovery in an individual. This might lead to the conclusion that certain individuals, classified as resilient, may have some increased innate capacity (plasticity), above and beyond normative levels, to recover from environmental insults that impact the brain. This view of resilience conceives of adversity in the environment as "bad" for the brain, with recovery as an innate property of the brain itself. This perspective, however, does not

consider the impact of a positive environment, or of the individual's active attempts at coping, on such recovery (Cicchetti, 2002; Cicchetti & Rogosch, 1997).

Another conceptualization of resilience would be one of greater than normative resistance to the impact of environmental adversity on the brain, such that resilient individuals may not succumb to the potentially damaging effects that adversity may have on the brain and other biological systems. This view of brain-adversity interaction would not strictly be classified as involving neural plasticity. Thus, for these individuals, the term recovery of function may not apply, in that they did not "lose" function at all. Despite the fact that this distinction may seem trivial, it may lead to important theoretical implications when considering the contribution of biology, and, in particular, processes described as neural plasticity, to resilience. Although quite general, the distinction between these two formulations of resilience also can generate important research questions concerning the relation of neural plasticity to resilience. Such questions underscore the importance of utilizing longitudinal research designs that can begin to examine the bidirectional relation between the brain's capacity to either resist damage from adversity versus its restorative capabilities.

Investigating Neural Plasticity and Resilience

The rapid growth in sophisticated techniques that permit imaging of the brain directly has resulted in the availability of a variety of methodologies to developmental psychopathology researchers, many of which could be utilized to examine neural plasticity, as well as brain structure and function, in detail. These new tools make it possible to now undertake empirical investigations of the relation between neural plasticity and resilience, perhaps enabling an examination of the direct linkage of these two processes. Questions about how neural plasticity may play a role in the development and maintenance of resilient functioning could be addressed, as well as whether the mechanisms of neural plasticity may operate differently in individuals classified as resilient.

Included among these new tools are: ERPs, magnetoencephalography (MEG), MRI, fMRI, positron emission tomography (PET), single-photon emission-computed tomography (SPECT), and magnetic resonance spectroscopy (MRS). Diverse information about the brain that is correlated with neural structure and functioning can be obtained by these various imaging techniques, including: (1) brain metabolic processes, such as cerebral blood flow and blood volume, and glucose metabolic rate; (2) bio-

chemical changes within brain cells, such as changes in neurotransmitter receptors; and (3) a sharp temporal resolution of brain functioning.

Among the compelling questions about resilient adaptation that could potentially be addressed utilizing brain imaging methodologies are: (1) Is brain structure and function different in resilient and nonresilient children matched on experiences of adversity? (2) Is the brain structure and function of resilient individuals who have experienced adversity different from normal children reared in nonadverse environments? (3) Are particular areas of the brain more likely to be activated in resilient than in nonresilient functioning during challenging or stressful tasks? (4) What aspects of brain structure and function differentiate individuals who function resiliently, despite experiencing early adversity, from those who function in a nonresilient fashion and who encounter adversity early in life (i.e., what is the role of early experience?) (5) Are there sensitive periods beyond which the achievement of resilience is improbable or is resilience possible to achieve across the life span? and (6) Are there changes over time in brain structure and/or functioning in individuals classified as resilient that may reflect processes of neural plasticity? The inclusion of neuroimaging techniques to the existing predominantly psychological approaches to charting the pathways to resilience, along with the biological and molecular genetic methods discussed next, results in many exciting discoveries about the complex processes that eventuate in competent outcomes despite the experience of significant adversity.

Aside from investigating the proximal relation between resilience and neural plasticity, there are several neurobiologically mediated processes (e.g., cognition, neuroendocrine functioning) that may have a direct relation to resilient outcome, some of which is described in the following sections. Although such processes may have a clear impact on resilient functioning, neural plasticity may, to some degree, be the common, underlying mechanism that mediates the relation between such processes and resilience. The behavioral manifestations of two of these realms, emotion and cognition, have been extensively investigated and their relation to resilience documented. In the sections that follow, possible links between the biological aspects of these phenomena and resilience is described.

Emotion and Resilience

Emotion encompasses a wide range of behavioral expressions and associated biological processes that play a vital role in many aspects of human development and adaptation. There are at least three primary, interrelated functional

realms of emotion in humans, including perception, expression, and regulation of emotion. The first part of this section focuses on emotion regulation as a key factor in resilient outcome, while the second part reviews and examines the relation between cortical EEG asymmetry, emotion, and resilient functioning.

One important contributor to resilience at the level of individual characteristics, and often cited as a potential protective factor against adversity in studies of resilience, is the ability to regulate emotion. Emotion regulation is conceived as the intra- and extra-organismic processes by which emotional arousal is redirected, controlled, modulated, and modified to enable an individual to function adaptively in emotionally arousing situations (Cicchetti, Ackerman, & Izard, 1995; Cicchetti, Ganiban, & Barnett, 1991; Gross, 1998; Thompson, 1990). Factors, such as organizational changes in central nervous system functioning, the ontogenesis of neurological inhibition systems in the prefrontal cortex, cerebral hemisphere lateralization, the development of neurotransmitter systems, children's growing cognitive and representational skills, and the development of a coherent sense of self, are some of the important intrinsic factors that shape the development of emotion regulatory abilities (Cicchetti et al., 1991; Cole, Martin, & Dennis, 2004; Eisenberg, 2002; Fox, 1994; Fox & Davidson, 1984; Gross, 1998; Kelley & Stinus, 1984; Schore, 1994; Tucker, 1981). Extraorganismic factors that exert an influence on the ability to regulate emotion include increased parental response and tolerance of affect and the parents' socialization of affective displays during interactions (Cicchetti et al., 1991). A number of characteristics are often referred to in the context of emotion regulation, including emotional reactivity, stress reactivity, temperament, or positive and negative emotionality (e.g., Davidson, 2000; Masten et al., 1999; Masten, 2001; Watson & Clark, 1984). Generally, these constructs represent the function of a diverse set of associated brain and neuroendocrine systems, which act in concert to produce and modulate the behavioral manifestations of an individual's response to emotional challenges and stressors.

There is an unfortunate paucity of empirical studies or conceptual work directly addressing if and how emotion and the regulation of emotion may serve as a protective factor in resilience. One of the primary questions involves whether individuals classified as resilient are to a large degree impervious to the typically insidious effects of stress, a view of resilient individuals as "invulnerable" (cf. Luthar et al., 2000); alternatively, it may be more accurate to characterize resilience in this context as the unique ability to react to stress in an adaptive way. Also important is the

question of how resilient individuals manifest adaptation in the face of stress and adversity at the level of biology.

Resilience, Emotional Reactivity, and Startle

Davidson (2000) has suggested that the capacity for rapid recovery from negative affective events, one specific aspect of emotion regulation, may constitute a critical component of resilient functioning. Davidson (1998a) outlines what he terms an affective chronometry, which is used to describe the time course of affective responding during experimental paradigms investigating emotion-modulated startle. In particular, Davidson (2000) has hypothesized that for resilient individuals, who tend to maintain high levels of positive affect and well-being in the context of adversity, negative affect does not persist. Thus, in this view, resilience does not entail never experiencing negative affect, but rather involves the ability to recover more quickly and to more easily return to a positive affective state, and also a heightened ability to learn from the experience of negative affect (Davidson, 2000). The specific biological underpinnings of the ability to recover quickly from negative affect are more than likely mediated by a fairly complex neural network, which has been shown to include (but is not limited to) the amygdala, several regions of the prefrontal cortex, brain stem structures, the hippocampus, and aspects of the cingulate cortex (Davidson, 2000; LeDoux, 1996, 2002).

The startle reflex is a methodological tool that has historically been utilized to examine individual differences in reaction to emotional stimuli, and is widely held to be a measure sensitive to individual differences in emotional reactivity. Generally, startle is an involuntary response to a sudden and intense tactile, visual, or acoustic stimulus that occurs across many species (Koch, 1999; Landis & Hunt, 1939). The response pattern consists of a fast twitch of facial and body muscles, which includes eye lid closure along with contraction of facial, neck, and other muscles. It is generally believed that this pattern of responding is a primitive reflex intended as a defensive response to protect against injury and as a preparation of a fight/flight response (Koch, 1999). The startle response can be easily measured in humans by recording the timing and intensity of the eye blink, which is the typical manifestation of the startle reflex.

The neuronal circuitry underlying the acoustic startle reflex is well understood in rodents and is relatively straightforward. It consists of an afferent pathway from the cochlear root neurons in the inner ear to the neurons in the nucleus reticularis pontis caudalis, and then to the motoneurons in the facial motor nucleus or the spinal cord (in

the case of the whole body startle; Davis, Walker, & Lee, 1999). However, other investigators have attributed the startle reflex to a slightly more complex pathway, which may include other brain stem structures, such as the dorsal and ventral cochlear nucleus, the lateral superior olive, and the ventrolateral tegmental nucleus (see Koch, 1999, for a review). Although the neural pathway mediating the startle reflex in humans may be somewhat more complex, it is nonetheless analogous in function to the rodent model.

A vast body of research has consistently and reliably demonstrated that the startle reflex can be modulated with presentation of emotional stimuli in conjunction with the startle stimulus (e.g., Bradley, Cuthbert, & Lang, 1993; Cuthbert, Bradley, & Lang, 1996; Lang, 1995; Vanman, Boehmelt, Dawson, & Schell, 1996). Consistent findings in both animal and human research have shown that the startle reflex is amplified when accompanied by negative emotional stimuli and, conversely, the magnitude of the startle reflex is attenuated when the startle-inducing stimuli are accompanied by positive emotional stimuli.

Modulation of the startle reflex due to emotional context implies that a secondary circuit modulates the primary reflex pathway described. It appears that the central nucleus of the amygdala is critically involved in some forms of fear-potentiated startle, via a descending pathway from this structure to the nucleus pontine reticularis in the brain stem (Davis, 1992). Lesions of the central nucleus of the amygdala have been shown to block the fear-potentiated portion of the startle response, but not the baseline (e.g., Campeau & Davis, 1995; Vrana, Spence, & Lang, 1988). In addition, based on anatomical and lesion data, other structures have been implicated in the potentiation of the startle response, including the central gray and the bed nucleus of the stria terminalis, depending on the type of startle-enhancing stimuli employed (Davis et al., 1999). There has been less work directly examining the mechanism for the attenuated startle response seen with presentation of positive emotional stimuli, but it would appear likely that the amygdala also plays a central role in this phenomenon.

Investigators have examined individual differences in the human startle reflex in a variety of populations suffering from the sequelae of trauma or who are at risk for anxiety, including individuals with posttraumatic stress disorder (PTSD; e.g., Grillon, Morgan, Southwick, Davis, & Charney, 1996; C. A. Morgan, Grillon, Southwick, Davis, & Charney, 1996). In the context of threat, male combat veterans diagnosed with PTSD exhibited an exaggerated startle response. However, there are conflicting results in studies of baseline startle response (i.e., startle reflex, induced without a threat of aversive stimulus) in

those with PTSD, with some investigations showing exaggerated baseline startle (e.g., Orr, Lasko, Shalev, & Pitman, 1995), and others revealing normal baseline startle (e.g., Orr, Solomon, Peri, Pitman, & Shalev, 1997). Women with PTSD resulting from sexual assault were found to have an exaggerated baseline startle response (C. A. Morgan, Grillon, Lubin, & Southwick, 1997). However, women with PTSD associated with childhood sexual abuse had a normal startle response (Metzger et al., 1999). These conflicting results have been attributed to differences in the aversive, threatening, or stressful context of the experiment (Grillon, Morgan, Davis, & Southwick, 1998).

In addition to the fairly extensive literature on startle and adults with PTSD, a few studies have examined the startle response in children with this disorder. One such investigation examined the startle response in a small sample of children with PTSD, aged 8 to 13 years (Ornitz & Pynoos, 1989). These investigators found a reduced baseline startle amplitude in both boys and girls compared to a group of control children. These findings, which are not consistent with findings of exaggerated startle in adults with PTSD, suggest that the age at which the PTSD-inducing trauma is experienced may have an impact on the type of effect seen in subsequent baseline and modification of startle responsiveness. In a startle study of adolescents, male offspring of parents with anxiety disorders were shown to have an increased fear-potentiated startle response (in a contextual threat condition) compared to low-risk control subjects (Grillon, Dierker, & Merikangas, 1998). The baseline startle magnitude was not different for the high-risk males. However, in this study, a sex difference emerged where female offspring of parents with anxiety disorders did not show elevated startle magnitude in the threat condition but exhibited elevated baseline startle magnitude. This is in contrast to an earlier study by Grillon, Dierker, and Merikangas (1997) where both male and female offspring of parents with anxiety disorders showed exaggerated baseline startle magnitude compared to a group of low-risk control children. However, the subjects in the latter study were several years younger than those in the Grillon, Dierker, et al. (1998) study. These authors suggest that the sex difference either may be a result of differences in brain structures that underlie affective responses to threat, or that development of those vulnerable to anxiety may proceed differently for males and females. Despite the discrepant findings obtained in these studies, which may be attributable to methodological differences, in general, the results of investigations with individuals diagnosed with PTSD or at risk for anxiety disorders have implied that startle reactivity may reflect the impact of en-

vironmental stressors on the brain systems mediating startle, and may in fact serve as a vulnerability marker for the development of anxiety disorders (Grillon et al., 1996).

In a recent investigation, the first of its kind, Klorman, Cicchetti, Thatcher, and Ison (2003) examined the baseline startle response in a large sample of children maltreated by their caregivers and a group of nonmaltreated comparison children. In this study, physically abused boys demonstrated a smaller startle-reflex amplitude and slower onset latency than did demographically matched nonmaltreated comparison children, consistent with findings in Ornitz and Pynoos (1989). In contrast, the younger maltreated girls in this sample demonstrated smaller startle amplitudes than younger comparison girls, whereas the older maltreated girls showed larger startle response magnitudes than did the nonmaltreated comparison girls of similar ages. The findings for the boys in this study are suggestive of a generalized defensive reaction that may lead to reduced responsiveness to noxious stimulation and subsequent down-regulation of the startle response that may be linked to reduced cortisol levels (Klorman et al., 2003). However, the findings for the girls in this sample are more difficult to interpret, given the relative dearth of studies investigating startle in traumatized women with PTSD, as well as the differences in the trauma experienced by men (e.g., combat) and women (e.g., sexual abuse/assault) with PTSD enrolled in most studies of startle.

Although there are some inconsistencies in the literature concerning the impact of adversity on the startle reflex, there is evidence to indicate that exogenous environmental influences do reliably effect this reflex and the underlying brain stem network that modulates this response. In particular, investigation of emotion-modulated startle is yet another tool that could be employed to further our understanding of the role of emotional regulation and reactivity in the promotion of resilience. Basic investigations of emotion-modulated acoustic startle could examine individual differences in the modulation of startle reactivity in the context of positive and negative foreground stimuli, such as emotionally toned pictures from the International Affective Picture System (IAPS; Lang, Bradley, & Cuthbert, 1995). Given that there is some Q-sort personality data indicating that individuals classified as resilient are more successful with emotion regulation (e.g., Cicchetti & Rogosch, 1997; Cicchetti, Rogosch, Lynch, & Holt, 1993; Flores, Cicchetti, & Rogosch, 2005), one prediction that could be tested would be that individuals manifesting resilient functioning would display less overall increase in magnitude of the blink response when presented with unpleasant pictures than would individuals not

classified as resilient but with equivalent levels of exposure to adversity.

Davidson (2000) has employed emotion-modulated startle to examine the role of the time course in affective responding and has indicated that this detailed analysis may contribute to our understanding of resilience. Davidson (2000) has suggested that by placing the acoustic-startle probes at various points before, during, and after the presentation of the emotional stimulus, then, in addition to the measurement of the response itself, the anticipatory and the recovery phases can be measured. Davidson (2000) has hypothesized that a rapid recovery phase after negative emotional stimuli is important in the development of resilience. Such a scenario suggests that negative affect, although experienced by resilient individuals, does not persist, and may be part of a ubiquitous predisposition for rapid recovery in multiple biological systems after exposure to negative and/or stressful experiences (Davidson, 2000).

Hemispheric EEG Asymmetry

Another area of emotion research directly involving the brain that may hold promise for the study of resilience is examining hemispheric asymmetries in cortical EEG activity, where a growing body of evidence has indicated differential roles for the left and right prefrontal cortex in emotion (Hugdahl & Davidson, 2003). In general, it appears that the left hemisphere participates more heavily in positive affect, whereas the right hemisphere mediates negative emotion (see reviews by Davidson, Ekman, Saron, Senulis, & Friesen, 1990; and Fox, 1991). Several investigators have found that induced positive and negative affective states can reliably shift hemispheric asymmetry (e.g., Ahern & Schwartz, 1985; Davidson et al., 1990; Jones & Fox, 1992). Negative affect induced by showing negatively toned stimuli (often in the form of film clips) increases relative right prefrontal activation as measured by EEG, while positive affect resulting from viewing positive stimuli is associated with increased activation in left prefrontal. This effect also has been demonstrated using PET to measure regional glucose metabolism, a by-product of increased neuronal activity (Sutton, Davidson, Donzella, Irwin, & Dotts, 1997; see also Pizzagalli, Shackman, & Davidson, 2003, for a selective review of PET and fMRI investigations on human emotion that have discovered lateralized activations).

In addition, many investigations have found an association between dispositional affective style and baseline levels of asymmetric activation in the prefrontal cortex (e.g., Sutton & Davidson, 1997; Tomarken, Davidson, Wheeler, & Doss, 1992). Generally, individuals with greater left

frontal activation report more positive affect than those with greater right frontal activation. Other work has shown that individuals who vary in resting prefrontal EEG activation asymmetry respond differently to positive and negative emotional stimuli (e.g., Tomarken, Davidson, & Henriques, 1990; Wheeler, Davidson, & Tomarken, 1993). Specifically, Wheeler et al. (1993) found that subjects with greater relative left hemisphere activation reported more positive affect when viewing positively toned film clips and less negative affect after viewing negatively toned film clips. Thus, fairly strong experimental evidence has suggested that not only do negative and positive emotion exert an impact on relative left-right activation of prefrontal regions, but also that baseline anterior activation asymmetry is associated with differences in emotional response.

Similar results concerning frontal EEG asymmetry have been demonstrated in infants and children. For example, studies of infants have generally reported increased right frontal EEG activity during the expression of negative emotions, such as crying and sadness, and increased left frontal activation during the expression of what are termed approach emotions, such as happiness (e.g., Bell & Fox, 1994; Dawson, Panagiotides, Klinger, & Hill, 1992). Hemispheric asymmetry in EEG activity also has been observed in children of depressed mothers, with infants and toddlers of mothers experiencing depressive symptomatology showing reduced left frontal EEG activation during baseline (e.g., Dawson, Grofer Klinger, Panagiotides, Hill, & Spieker, 1992; Dawson, Frey, Panagiotides, Osterling, & Hessler, 1997; Dawson et al., 1999; Field, Fox, Pickens, & Nawrocki, 1995; Jones, Field, Fox, Lundy, & Davalos, 1997). These findings appear to be analogous with Davidson's evidence of frontal EEG asymmetry in normal adults suggesting that the left hemisphere is generally involved with positive affect. It is conceivable that the inability of mothers with depressive disorder to provide their children with adequate positive emotion and to facilitate their children's self-regulation of emotion not only affects their children's behavioral regulation capacities but also exerts an impact on the neurobiological systems that underlie these abilities (Cicchetti et al., 1991; Cicchetti & Toth, 1998; Dawson, 1994).

Finally, hemispheric EEG asymmetry has been observed in adults with depression (e.g., Allen, Iacono, Depue, & Arbisi, 1993; Henriques & Davidson, 1991). Generally, individuals diagnosed with depression have been shown to exhibit decreased left prefrontal EEG activation, although some studies have failed to replicate this finding (e.g., Reid, Duke, & Allen, 1998). However, utilizing PET to assess regional glucose metabolism, Baxter et al. (1989) reported that individuals diagnosed with depression demonstrated re-

duced left frontal activity; similar findings have been reported by Drevets et al. (1997).

Resilience and Hemispheric Asymmetry

Davidson and colleagues view individual differences in hemispheric asymmetry in prefrontal activation as a contributing factor to the development of affective style (Davidson, 1998a, 1998b). Further, Davidson (1998a, 1998b) characterizes such individual differences in hemispheric asymmetry in the context of depression as diatheses that might bias the affective style of an individual. In turn, this affective style bias may act as a risk factor for, or exacerbate a person's vulnerability to, depression.

Analogously, an important consideration is that any relation between hemispheric asymmetry and resilience is more than likely a distal one, with many intervening processes between asymmetry and the process of resilience. In addition, discussing a phenomenon, such as hemispheric asymmetry in the context of resilience, provides an opportunity to state that there is certainly no one single biological characteristic or phenomenon that is ascendant in the process of resilience over the course of development. Across time, the relative importance of various biological systems for promoting resilience may vary within an individual.

Given these caveats, one immediately obvious application of findings concerning emotion and hemispheric asymmetry for the study of resilience would be to examine individual differences in prefrontal hemispheric EEG activation in individuals who have experienced significant adversity to discern whether or not those classified as resilient based on their psychological profiles demonstrated a different pattern of EEG asymmetry than those not characterized as resilient. An often-cited group of individual characteristics predictive of good adaptation in the context of risk includes positive self-perception, a positive outlook on life, and a good sense of humor (Masten & Reed, 2002). Given the importance of these individual characteristics as protective factors, it would be reasonable to hypothesize that resilient individuals might show greater left frontal baseline EEG activity. Moreover, evidence of good emotion regulation skills and lower emotional reactivity in individuals classified as resilient could lead to the hypothesis that individuals labeled as resilient may display less reactivity to emotionally toned stimuli, as measured by changes in frontal EEG asymmetry.

Neuroendocrinology, Immunology, and Resilience

A significant amount of research with a variety of species, including rodents, nonhuman primates, and humans, has

been devoted to examining the effects that stress and adversity exert on the brain and neuroendocrine and immunological systems (for reviews, see Granger, Dreschel, & Shirtcliff, 2003; Gunnar, 1998; Kaufman, Plotsky, Nemeroff, & Charney, 2000; Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002; Ladd et al., 2000; McEwen, 2000; Meaney et al., 1996; Sanchez et al., 2001; Sapolsky, 1992, 1996), as well as on cognitive performance (Heffelfinger & Newcomer, 2001). However, and more relevant to resilience, the important task that lies ahead is discerning the protective processes that serve to moderate the impact of adversity on neurobiological systems, and discovering the mechanisms by which these palliative forces come into play (e.g., Charney, 2004).

To date, research that has been conducted with rodents and nonhuman primates has demonstrated that traumatic events experienced early in life can modify typical behavioral, neuroendocrine, and immunological responsiveness; brain morphology; gene expression; and neurochemistry (Meaney, 2001; Meaney et al., 1996; Sanchez et al., 2001). Work conducted with humans experiencing adversity, including children reared in orphanages, children who reside in lower-socioeconomic environments, and children who have been abused or neglected, reveals similar negative consequences on stress and brain systems, as well as gene expression (Caspi et al., 2002; Cicchetti & Rogosch, 2001a, 2001b; Cicchetti & Walker, 2001; DeBellis, 2001; DeBellis, Baum, et al., 1999a; DeBellis, Keshavan, et al., 1999b; Foley et al., 2004; Gallo & Matthews, 2003; Gunnar et al., 2001; Lupien, King, Meaney, & McEwen, 2001).

The activation of the HPA axis in response to physical and psychological perturbations is adaptive and critical for the survival of challenges to the organism's homeostasis. In this sense, the stress response can be said to serve a protective function (McEwen, 1998). However, the chronic mobilization of the stress response (i.e., hypercortisolism) also can exert damaging, even pathogenic, effects on neurons (e.g., neuronal atrophy, neurotoxicity, and neuroendangerment; Bremner, 1999; McEwen & Sapolsky, 1995; Sapolsky, 1996, 2000a, 2000b). Moreover, the elimination of glucocorticoids (i.e., hypocortisolism) also can cause damage to neurons (Gunnar & Vazquez, 2001; Heim, Ehlert, & Hellhammer, 2000).

One primary means through which hormones affect behavior is via their impact on gene expression (McEwen, 1994; Watson & Gametchu, 1999). Stress hormones have been shown to exert direct effects on the genes that control brain structure and function, including neuronal growth, neurotransmitter synthesis, receptor density and sensitivity, and neurotransmitter reuptake (McEwen, 1994; Wat-

son & Gametchu, 1999). The glucocorticoid receptors that reside in a cell's nucleus are responsible for the influence that stress hormones exert on the expression of genes that govern brain function (Watson & Gametchu, 1999). As noted earlier in this chapter, it has been demonstrated that chronic stress eventuates in a persistent inhibition of granule cell production and changes in the structure of the dentate gyrus, suggesting a mechanism whereby stress may alter hippocampal function (Gould & Tanapat, 1999).

Moreover, close, interpersonal relationships that are discordant also can be associated with the dysregulation of the immune system (Kiecolt-Glaser et al., 2002). Social stressors can cause neurotransmitters (e.g., the catecholamines) and stress hormones to elevate substantially; furthermore, these hormones and neuromodulators exert multiple immunomodulatory effects on the functioning of the immune system (Granger et al., 2003; Segerstrom, 2000). In addition, the experience of negative emotions, such as anxiety and depression, can exert a direct impact on the cells of the immune system by either up or down regulating the secretion of proinflammatory cytokines (Granger et al., 2003; Kiecolt-Glaser et al., 2002).

Importantly, research conducted with rodents demonstrates that early social experiences do not exert immutable negative consequences for the developing nervous system. For example, the results of investigations carried out by Francis et al. (1996; see also Meaney, 2001) have revealed that interventions, such as providing opportunities for maternal handling, licking, and grooming to rat pups who had experienced prolonged periods of maternal separation early in life, alter the central circuitry of emotion that results in these rat pups having a decreased responsivity to stress in later life (Meaney, 2001). Thus, these early interventions underscore the plasticity of emotion circuitry in rat pups. It remains to be discovered whether this circuitry is capable of being modified if interventions with rat pups who have experienced pronounced periods of early maternal separation are not provided until childhood or in adulthood.

In research with humans, Nachmias, Gunnar, Mangelsdorf, Parritz, and Buss (1996) found that a secure mother-child attachment relationship buffered the functioning of the HPA axis. Specifically, securely attached toddlers who were behaviorally inhibited did not exhibit significant elevations in cortisol, whereas insecurely attached toddlers who were behaviorally inhibited displayed significant elevations in cortisol. In addition, Gunnar, Brodersen, Nachmias, Buss, and Rigatuso (1996) discovered that attachment security moderated the cortisol response to the distress of inoculation. In particular, Gunnar et al. (1996) found that the combination of behavioral inhibition and

insecure attachment resulted in these toddlers exhibiting elevated cortisol levels post inoculation. Taken together, these findings suggest that the sensitive caretaking that is characteristic of the mothers of securely attached youngsters may play an important role in the modulation of the HPA axis, especially if the child possesses a behaviorally inhibited temperament.

Gunnar and colleagues (2001) found that six and a half years postadoption, children who had been reared in Romanian orphanages for greater than 8 months in their 1st year of life had higher morning (AM) basal cortisol levels than did Romanian orphans who were adopted within the first 4 months of their lives. Moreover, the longer that the Romanian orphan children were institutionalized beyond 8 months, the higher were their AM basal cortisol levels. Intervention studies would help to ascertain whether the cortisol levels of the orphans who had been institutionalized greater than 8 months were modifiable, or whether such prolonged institutionalization exerted indelible effects on the HPA axis. Likewise, longitudinal follow-up of these children who were reared in Romanian orphanages could reveal whether the functioning of the HPA axis is stable and whether those children adopted before 4 months exhibit resilient functioning, whereas those who were adopted after 8 months of institutionalization display non-resilient functioning in middle childhood. Furthermore, assessments of the quality of the parent-child relationship and of family stress could enable the detection of some of the mediators linking early experience and later outcome.

Despite the fact that the experience of persistent stress is usually associated with deleterious biological and psychological outcomes, not all organisms are affected in the same fashion (Sapolsky, 1994). It is important to note, in keeping with the general systems theory concept of multifinality, that similar stressful experiences may not exert the same impact on biological and psychological functioning in different organisms. Furthermore, the same outcomes, be they positive or negative, that were the result of stressful experiences may have eventuated from different developmental pathways (i.e., equifinality).

The confluence of a number of factors, including physical status, genetic makeup, prior experience, and developmental history, determine the differential ways in which organisms may react to a stressful event (McEwen, 1994; Sapolsky, 1994). In particular, the combination of genetic makeup, previous experience, and developmental history could either sensitize or protect the organism from subsequent stressful challenges. Additionally, more long-term stress responsiveness is characterized by interindividual variability and is related, in part, to experiential influences

on gene expression (Meaney, 2001; Meaney et al., 1996). Thus, there are multiple converging pathways—including not only the neural networks that are activated by physical, psychological, and immunological stressors, but also the influence of genetics, early experience, and ongoing life events that determine the neural response to different stressors (McEwen, 1994; Sapolsky, 1994).

The ability to measure the functioning of the HPA axis through a variety of techniques enables researchers to more precisely quantify the “stress” component of diathesis-stress models of psychopathology and to examine the relation between stress and mental disorder. Moreover, the utilization of salivary biomarkers as relatively noninvasive measures of neuroendocrine and immune functioning makes it feasible for a larger number of researchers, including those investigating the pathways to, and correlates of, resilience, to implement neuroendocrinological and immunological assays into their work.

Among the most widely employed existing measures of neuroendocrine regulation are stress-reactivity paradigms that may increase HPA axis activity. There are several such procedures that are commonly utilized in the literature on HPA axis regulation. These include the Cold Pressor Test (CPT; Bullinger et al., 1984; Edelson & Robertson, 1986), the Trier Social Stress Test (TSST; Kirschbaum, Pirke, & Hellhammer, 1993), and maternal separation paradigms (Nachmias et al., 1996). For such paradigms, saliva for subsequent cortisol assaying is typically collected three times—once at baseline, 25 to 30 minutes poststressor, and once more 25 to 30 minutes after the second collection. A number of procedures also are used to index other aspects of HPA functioning, including assessments of the diurnal regulation of cortisol, 24-hour circadian rhythm collections, and biochemical challenge tests (Vazquez, 1998). Recently, salivary alpha-amylase, a surrogate marker of the sympathetic nervous system component of the stress response, has been employed to test biosocial models of stress vulnerability (Granger et al., in press). It has been discovered that patterns of salivary alpha-amylase stress reactivity differ from those obtained utilizing salivary cortisol measurements. These findings suggest that it is important to integrate measurement of the adrenergic component of the sympathetic nervous system, as indexed by alpha amylase, into investigations of normal development and psychopathology (Granger et al., in press). Furthermore, scientists have begun to examine multiple salivary biomarkers of neuroendocrine (e.g., cortisol and dehydroepiandrosterone [DHEA]) and immune functioning (e.g., IgA, Neopterin, and possibly cytokines), as well as neuroendocrine-immune system interactions (e.g., Granger

et al., 2003; Granger, Hood, Dreschel, Sergeant, & Likos, 2001; Schwartz, Granger, Susman, Gunnar, & Laird, 1998).

The incorporation of these readily obtainable salivary biomarkers in prospective longitudinal studies that also collect psychological indicators of resilient functioning may serve to enhance the understanding of the pathways to competent adaptation in the face of adverse circumstance. For example, are individuals who function resiliently more likely to return to baseline levels of neuroendocrine functioning more quickly in stress-reactivity paradigms than are individuals who are not functioning in a resilient manner? Are individuals who function in a resilient fashion less likely to develop negative neurobiological sequelae despite experiencing extreme stress? When individuals who function resiliently do evidence harmful biological sequelae, do these individuals recover their function more readily than do nonresilient individuals (i.e., do individuals who function in a resilient manner manifest greater neural plasticity)? Finally, are individuals who function resiliently better able to regulate their allostatic load—the cumulative long-term effects of physiological responses to stress (McEwen, 1998; McEwen & Stellar, 1993)?

Because they play critical roles in numerous adaptive and harmful physiological outcomes, the neuroendocrine system and the sympathetic nervous system are considered among the major mediators of allostatic processes. Repetitive social challenges in a child's environment, such as being reared in an institution and being abused or neglected, can cause disruptions in basic homeostatic and regulatory processes that are central to the maintenance of optimal physical and mental health (Repetti, Taylor, & Seeman, 2002). It is conceivable (and indeed there is some evidence at the psychological level; see Cicchetti & Rogosch, 1997) that individuals who function resiliently are more adroit at coping with stress. Relatedly, might the ability of resilient individuals to cope successfully with stress be associated with healthy, well-regulated immune functioning? For example, can the activation of the cytokines, effector molecules that are hypothesized to mediate our classic sensory functions, affect developmental plasticity via their effect on emotional, cognitive, and behavioral processes (Granger et al., 2003)? Measures of neuroendocrine regulation and reactivity and of immune function must increasingly become a part of the measurement batteries used in studies on resilient adaptation.

Cognitive Processing and Resilience

A consistent finding across several studies of resilience is that better intellectual skills are associated with more pos-

itive outcomes in individuals reared in adverse environments (e.g., Cicchetti & Rogosch, 1997; Garmezy et al., 1984; Luthar & Zigler, 1992; Masten et al., 1999; White, Moffitt, & Silva, 1989). In these studies of resilience, intellectual functioning is primarily measured with traditional measures of intellectual ability (e.g., the Peabody Picture Vocabulary Test-Revised [PPVT-R]; Dunn & Dunn, 1981), that are assumed to reflect a heterogeneous set of underlying cognitive processes that are manifested behaviorally as intelligence and adaptive functioning. These processes may include, but are not limited to, memory, attention, reasoning, and behavioral inhibition. Unfortunately, the global nature of most of these indices has, for the most part, prohibited a direct examination of which (or if) individual components of cognition may be associated with resilience.

However, some preliminary work has examined the contribution of specific facets of cognitive functioning to resilient outcomes (Curtis, 2000). This investigation was, in part, based on previous findings indicating an association between cognitive functioning and academic and social competence (Pellegrini, Masten, Garmezy, & Ferrarese, 1987). Curtis (2000) examined the relation between resilience and a set of empirically derived components of cognition, including some aspects of attention, problem solving, inhibition, creative thinking, and humor in the Project Competence cohort, a longitudinal investigation of the correlates and pathways of adaptive functioning in the face of adversity (e.g., Masten et al., 1999). These components were drawn from several measures of cognitive functioning that were administered to a subset of 90 participants in the initial assessment of this cohort in the early 1980s, when they were approximately 8 years of age.

Three composite scales of cognitive functioning were derived from these measures through a process of correlation, factor analysis, and reliability analyses: verbal ability, problem solving, and attentional functioning. Performance on these composite scales was compared across individuals classified during adolescence into one of three groups based on their level of competence across salient developmental domains and adversity. This work demonstrated that individuals classified as resilient (high adversity, high competence) during adolescence had better problem-solving ability in middle childhood, and also performed better on some aspects of attentional functioning than individuals in the same cohort classified as maladaptive (high adversity, low competence). Superior performance on the measures making up this composite may reflect good executive functioning, which would include planning ability, logic,

and general problem-solving skills in the context of interpersonal relationships.

These findings suggest that good functioning on certain cognitive processes is associated with resilience in this cohort, and also begin to provide a more detailed picture of what aspects of intelligence and superior intellectual functioning serve to promote resilience. However, considering the extreme complexity of the specific operations referred to as cognition, the problem-solving composite scale from this study is very nonspecific. A variety of interdependent cognitive skills involving the coordinated action of multiple neural networks are required to solve the problems associated with this scale and other traditional assessments of higher-order cognitive processes. In general, it is difficult to extrapolate from findings from paper and pencil measures of intellectual functioning to particular cognitive processes and brain structures that may be involved in such functioning; moreover, traditional tests of intellectual and cognitive functioning have not been tied to specific functional brain regions (other than the obvious linkage between the frontal cortex and higher-cognitive functioning). Neurocognitive measures that are able to differentiate performance on specific, circumscribed cognitive processes need to be employed in order to determine in more detail the cognitive abilities that may be associated with resilience, or that might serve as protective factors for good functioning in the context of adversity. In addition, without the application of brain-imaging techniques to determine the structural and functional attributes of specific neural substrates of cognitive abilities that may be associated with resilience, or at the very least data from neuropsychological measures that include tasks that have been tied to particular brain regions, it is impossible to determine with any degree of certainty which specific cognitive abilities might be associated with resilient functioning.

Assessment of Links between Cognition and Resilience

One assessment instrument in particular, the Cambridge Neuropsychological Testing Automated Battery (CANTAB), a computer-based neuropsychological test of nonverbal memory and executive functioning, would be well suited to examining the relation between cognitive functioning and resilience (Fray, Robbins, & Sahakian, 1996). Linkages between specific CANTAB tasks and neuroanatomical systems have been established in neuroimaging studies of adults (Owen, Evans, & Petrides, 1996). This assessment was originally developed to mea-

sure cognitive functioning in geriatric populations, although normative data on children's performance on the CANTAB has recently been published (Luciana & Nelson, 2002). This assessment instrument, while providing only an indirect assessment of brain functioning, would nonetheless be a relatively inexpensive and highly accessible option for examining linkages between specific aspects of cognition and resilience. Not only is CANTAB a highly sensitive and well-validated measure of a wide range of cognitive processes, but also it potentially would allow for the investigation of the differential contribution of a number of different types of cognitive processes to resilient functioning. For example, the CANTAB could be employed to examine whether superior ability in a particular type of memory process (e.g., spatial memory span, spatial working memory, recognition memory) contributed to resilient functioning, or, alternatively, whether those who exhibit resilient functioning may exhibit high functioning in multiple realms of memory. Also, one could examine the possible differential contribution of various types of executive functioning (e.g., inhibition, logical planning, and memory) to resilient functioning.

Brain Imaging, Cognition, and Resilience

Given the consistent association between greater intelligence and resilient functioning (e.g., Cicchetti & Rogosch, 1997; Garmezy et al., 1984; Luthar & Zigler, 1992; Masten et al., 1999), previous studies examining brain functioning in those of superior intellectual ability may have some relevance for the study of resilience. A fairly well-established body of research has directly examined brain functioning in individuals with superior intellectual ability, and to date most investigations directly examining brain activity and intelligence have suggested that the brains of individuals with superior intellectual abilities are less active during problem solving than those of individuals with average intellectual abilities (e.g., Haier, Siegel, Tang, Abel, & Buschbaum, 1992; Jausovec, 2000; Jausovec & Jausovec, 2001; O'Boyle, Benbow, & Alexander, 1995). In particular, PET studies have shown that brain metabolic activity is lower during problem-solving tasks for individuals of higher intelligence (e.g., Haier et al., 1988), whereas studies of EEG activity have shown that individuals with greater intellectual ability have less complex and more coherent EEG waveforms (Anokhin, Lutzenberger, & Birbaumer, 1999; Jausovec, 2000). In addition, more intelligent individuals show a decrease in the volume of activated gray matter during an oddball task (a simple discrimination task where the participant is instructed to respond to a

low frequency event, such as the infrequent presentation, e.g., 20% probability, of the letter x in the context of the frequent presentation, e.g., 80% probability, of another letter), as shown using a method of low-resolution brain electromagnetic tomography (LORETA; Jausovec & Jausovec, 2001; Pascual-Marqui, Michel, & Lehmann, 1994).

These findings are generally interpreted as reflecting greater brain efficiency in those of superior intellectual ability, whereby brain areas not needed for good performance on a particular task are not utilized, while those areas specifically relevant to the task are used in a more concentrated fashion (Haier et al., 1992; Jausovec & Jausovec, 2000, 2001). In effect, fewer and more specific brain networks are activated during problem-solving tasks.

Other investigations have recently examined the location of the neural substrate mediating intellectual functioning. In a PET study by Duncan et al. (2000), these investigators found that a diverse set of tasks designed to tap general intelligence (Spearman's *g*), compared to a set of control tasks, were associated with selective neural activation in the lateral frontal cortex. This result suggests that general intelligence, rather than requiring the use of multiple brain areas, may derive from a specific neural system located in the frontal cortex that mediates many different types of cognitive demands. Gray, Chabris, and Braver (2003) employed an event-related fMRI design to examine the hypothesis that general fluid intelligence is mediated by brain regions that support attentional functioning. Utilizing a relatively large number of subjects ($n = 48$) for an fMRI study, Gray et al. (2003) were able to apply a multiple regression analysis to localize brain functioning to primarily the lateral prefrontal cortex during a demanding working memory task designed to be a test of general fluid intelligence. However, contradictory to many studies showing less brain activity in those with superior intellectual ability during problem solving, Gray et al. (2003) found that higher fluid intelligence, indexed by performance on Raven's Advanced Progressive Matrices (APM; Raven, Raven, & Court, 1998), was associated with greater activity in the lateral prefrontal cortex during a fairly difficult working memory task. It is possible that this finding is a result of the relatively highly challenging nature of the task administered, in comparison to more simple tasks employed in other studies of brain function and superior intelligence.

The ERP is an index of central nervous system functioning thought to reflect the underlying neurological processing of discrete stimuli (Hillyard & Picton, 1987). ERPs represent scalp-derived changes in brain electrical activity, believed to be generated by changes in membrane poten-

tials of nerve cells, thus reflecting activity associated with neuronal connections (Hugdahl, 1995; Nelson & Bloom, 1997). ERP data is collected across a discrete temporal window (typically a few seconds), obtained by averaging time-locked segments of the EEG that follow or precede the presentation of a stimulus. In this manner, ERPs allow for monitoring of neural activity associated with cognitive processing in real time (Donchin, Karis, Bashore, Coles, & Gratton, 1986). Their particular strength lies in the high temporal resolution they provide, allowing for a finely detailed examination of the timing of cognitive operations in the brain at the level of milliseconds.

Studies utilizing ERPs to examine brain electrophysiology and intelligence have consistently demonstrated that the amount of time for ERP wave forms to reach their peak amplitude is negatively correlated with IQ, indicating that cognitive operations may be occurring more rapidly in the brains of individuals with greater intellectual ability (e.g., Barrett & Eysenck, 1994; Bazana & Stelmack, 2002; Burns, Nettelbeck, & Cooper, 2000; Jausovec & Jausovec, 2001). In particular, it appears that this difference occurs in the P300 ERP component, and not in earlier occurring components associated with lower-level sensory processes (Jausovec & Jausovec, 2001). The P300 is generally viewed as reflecting cognitive processing related to learning as well as the transfer of sensory information about a stimulus into working memory, referred to as context updating (Donchin & Coles, 1988). Latency of the P300 is associated with the amount of time it takes for an individual to evaluate the novelty or significance of a stimulus, and is typically prolonged in individuals with neurodegenerative disorders (Donchin & Coles, 1988; Hugdahl, 1995).

Other investigations have measured the relation between resting brain activity and intellectual ability. Findings from these studies have been less conclusive, but, generally, greater EEG coherence has been shown to be associated with increased intellectual ability. It is assumed that increased coherence again reflects more efficient utilization of neural networks.

Unfortunately, most studies examining the relation between intelligence and brain functioning have not been designed to delineate the relation between brain functioning and particular aspects of intelligence. Hence, the tasks employed during these studies have not been specific to any particular cognitive process, but rather have been chosen to reflect intellectual ability in general. In addition, creativity has been controlled for in many of these studies, given that persons high on measures of creativity differ from those high only on intelligence with respect to

brain activity during problem-solving tasks (e.g., Carlsson, Wendt, & Risberg, 2000; Jausovec, 2000).

A major difficulty in examining the role of intelligence in promoting resilience is the vastly complex constellation of cognitive and executive functioning skills possibly associated with performance on psychometric measures of intelligence. The association between performance on some executive function tasks and IQ is moderate at best; whereas some aspects of executive functioning appear not to have a relation with IQ (e.g., Luciana & Nelson, 2002), other studies have suggested that executive functioning, subserved by the frontal cortex, is one of the underlying essential functions of creativity (Carlsson et al., 2000). Finally, many basic cognitive processes, such as attention and memory, are clearly associated with psychometric indices of intellectual functioning, but exactly how is unclear.

Thus, the first step in examining the nature of the strong association of intellectual ability with resilience would be to determine which aspects of intellectual functioning were more or less important in their contribution to resilient functioning. For example, in the Curtis (2000) study, the verbal and performance scales of an intelligence assessment loaded on two different composites of cognitive functioning, with the performance scale differentiating resilient and nonresilient groups, whereas the verbal scale did not. More comprehensive neuropsychological assessment of resilient and nonresilient individuals, such as administration of entire IQ batteries rather than abbreviated versions, would be useful in determining which aspects of traditional psychometric intelligence were important in promoting resilience. Also, it is essential that many different components of cognition and executive functioning be assessed in order to determine what particular grouping of skills may be associated with resilience. It seems unlikely that any one aspect of cognition and executive functioning alone is the critical defining feature of resilience. Rather, it seems reasonable to hypothesize that strengths on a variety of cognitive and executive functions, such as memory, attention, flexible problem solving, and inhibition, contribute to resilient functioning. However, it is of critical importance to ascertain which of these processes does or does not contribute to resilience in order to inform prevention and intervention. Utilizing instruments, such as CANTAB, a measure of more subtle and specific aspects of neuropsychological functioning, is essential in the study of cognition, executive functioning, and resilience.

Going beyond traditional neuropsychological assessment, brain-imaging studies are an important methodology to apply to investigating the role of cognition and executive functioning in resilience. Although neuropsychological as-

sessments measure aspects of cognitive functioning and allow inferences to be drawn about the neural substrate(s) involved, it is essential to employ brain imaging in order to directly determine the temporal, structural, and functional aspects of cognition and the brain (Toga & Thompson, 2003). Brain imaging allows for the direct examination of the neural substrate involved with cognition and executive functioning in individuals classified as exhibiting resilient functioning. Neuroimaging methods, such as fMRI, also can be utilized to determine if aspects of brain functioning in such individuals are unique in some way compared to competent individuals not exposed to adversity.

In addition, ERPs also can be utilized to elucidate the possible relation between cognitive efficiency and resilience. In particular, two questions can be addressed. First, it would be useful to determine whether or not individuals classified as resilient demonstrate greater cognitive efficiency in general compared to individuals not demonstrating resilience. This could be accomplished by comparing peak latencies of the P300 during cognitive tasks, such as the oddball paradigm or a recognition memory task.

Secondly, it would be informative to compare cognitive efficiency on a variety of tasks to ascertain whether there is a specific type of cognitive function that resilient individuals are able to accomplish more efficiently, or if the efficiency is an overall strength, independent of the type of cognitive operation. In this regard, it also would be informative to compare resilient individuals with those exhibiting competent functioning but not exposed to adversity. It is possible that competent functioning, despite exposure to significant adversity, may be associated with cognitive efficiency in a different way than it is for individuals not exposed to adversity. This approach can help to elucidate, at the level of brain functioning, whether speed of processing is an underlying factor in resilience, and, if so, for which type of cognitive processes is this increased efficiency important in the context of resilient functioning.

Although ERPs are particularly advantageous in determining the chronology of neural processes, this methodology does not lend itself to the precise localization of these processes. FMRI, however, does enable the localization of brain functioning with relatively great precision (see Casey, Davidson, & Rosen, 2002 and de Haan & Thomas, 2002 for relevant reviews of this methodology). FMRI is a rapidly evolving technology that has exciting, but as of yet unexplored, potential in the study of resilience. In particular, application of this methodology would be extremely useful in examining questions about the role of cognition and executive functioning in promoting resilience. For example, it would enable the examination of whether cogni-

tive operations of those classified as resilient took place in the same or perhaps different brain systems than those experiencing adversity but not classified as resilient.

Additionally, fMRI would allow direct examination of the impact of adversity on brain structures, such as the hippocampus, which has been shown to have decreased volume in patients diagnosed with PTSD related to war combat exposure or childhood sexual and/or physical abuse (e.g., Bremner et al., 1995, 1997; Gurvits et al., 1996; Stein, Koverola, Hanna, Torchia, & McClarty, 1997; Villarreal et al., 2002). Although the cause of this volumetric reduction has not been definitively established (in fact, it is possible that reduced hippocampal volume precedes, and is a risk factor for, PTSD), the predominant view, proposed by Bremner (1999), is that reduced hippocampal volume is a result of neurotoxic effects linked to traumatic events. This neurotoxic process appears to be due to an interaction between elevated levels of glucocorticoids and excitatory neurotransmitters (e.g., glutamate), with the specific, targeted effect on the hippocampus due to its high concentration of glucocorticoid receptors (for review of this process, see McEwen & Magarinos, 1997).

In the case of individuals classified as resilient who, by definition, have been exposed to significant adversity or trauma, it would be reasonable to formulate two hypotheses: (1) As a result of this exposure to adversity over time, such individuals may have reduced hippocampal volume compared to controls but do not show expected behavioral deficits in memory. Memory functioning in these individuals may be mediated by other neuroanatomical structures and networks, thus compensating for possible diminished functional capacity of the hippocampus, or (2) Resilient individuals, despite exposure to adversity or trauma, do not have reduced hippocampal volume. In either case, volumetric MRI studies to ascertain the degree to which, if any, the hippocampus has reduced volume could be employed. In addition, functional brain imaging studies utilizing fMRI would be useful to ascertain what compensatory mechanisms are being employed (if reduced hippocampal volume were confirmed).

MRI diffusion tensor imaging (DTI), a relatively new technique that allows imaging of white matter tracts that connect neural tissue across brain areas, also holds great promise in studying cognition and resilience. DTI has provided evidence of differences in intercortical connectivity in individuals with neuropsychiatric disorders (e.g., Kubicki et al., 2002; Lim et al., 1999). Application of this technique to the study of resilience could potentially demonstrate differences between resilient individuals, non-resilient individuals exposed to adversity, and competent in-

dividuals not exposed to adversity in connectivity between regions of the cerebral cortex, possibly offering evidence of neural plasticity as one of the underlying mechanisms of resilient outcome.

Genetics and Resilience

From a genetic perspective, resilience can be conceptualized as the extent to which individuals at genetic risk for maladaptation and psychopathology are not affected (Garmezy & Streitman, 1974; Luthar et al., 2000; Rende & Plomin, 1993). Additionally, there may be genetic contributors to resilient adaptation that protect some individuals in families where there is a high genetic loading for developing maladaptation and mental disorder from succumbing to these deleterious outcomes. Moreover, genes are equally likely to serve a protective function against environmental insults for some individuals. Thus, it is apparent that genetic influences on maladaptation and psychopathology operate in a probabilistic and not a deterministic manner.

To date, there has been a paucity of investigations that have examined genetic contributors to resilient functioning. Rende and Plomin (1993) have explicated the ways in which the designs and methods of quantitative behavior genetics may be utilized to uncover the genetic and environmental contributions to resilience. Herein, we provide several examples of how molecular genetic techniques may be utilized to proffer insights into the pathways to resilient adaptation.

Buccal swab sampling procedures provide a relatively easy and painless method for collecting DNA from research participants (Freeman et al., 1997; Plomin & Rutter, 1998). The buccal swabs can be easily stored in the laboratory; subsequently, the DNA is purified, ideally as soon as possible, utilizing a DNA Extraction Kit. In the particular kit used in our laboratory, the extraction solution is aliquoted in 0.5 ml amounts into sterilized DNase and RNase free 1.5 ml microcentrifuge tubes, which are labeled and stored in a freezer at -80°C until usage. The equipment needed to extract and purify DNA is relatively inexpensive, and the methodology is not difficult to learn. Hence, it is quite feasible for researchers without expertise in molecular genetics to carry out DNA extraction in their own laboratory. Alternatively, collaborations with geneticists in universities or medical school settings could facilitate the application of these techniques.

Polymerase Chain Reaction (PCR) is a quick, fairly cost-efficient technique for producing an unlimited number of copies of any gene. The powerful duplication ability of PCR enables researchers to utilize tiny amounts of cells or

tissues (such as those obtained with the buccal swabbing technique) to amplify or copy DNA and to subsequently undertake molecular genetic analysis. Although PCR itself is not very expensive, the equipment necessary to conduct subsequent molecular genetic analyses, such as a gene sequencer, is substantially more costly. The relative ease with which DNA can be collected enables even developmental psychopathologists who are not well versed in molecular genetics to obtain DNA from participants and to examine the relation of this genetic material to normal, maladaptive, and resilient behavioral outcomes.

Recently, great progress has been made in the mechanisms involved in the study of gene expression. These advances provide exciting new opportunities for enhancing knowledge not only on the genesis and epigenesis of maladaptive development and mental disorders, but also of resilience. Molecular genetic methods now exist that enable researchers to investigate the expression of particular genes or of large numbers of genes simultaneously (so called "gene profiles"). Through the utilization of complementary DNA (or cDNA) microarrays, researchers can discover the type and quantity of messenger RNA (mRNA) being produced by a given cell, thereby indicating which genes are "turned on" (i.e., activated; Hacia & Collins, 1999; Mirnics, Middleton, Lewis, & Levitt, 2001; Raychaudhuri, Sutphin, Chang, & Altman, 2001). DNA microarrays can be utilized to index changes in the expression of genes that are essential for brain function (Greenberg, 2001; Walker & Walder, 2003). By examining the concurrent and longitudinal relations among environmental, gene expression, neurobiological, hormonal, and psychological processes in individuals who have experienced significant adversity, researchers may be in a stronger position to elucidate the development of resilient adaptation. Such multiple level of analysis investigations may reveal the mechanisms responsible for activating and inhibiting the expression of genes that are probabilistically associated with maladaptive developmental outcomes and psychopathology. Likewise, these multidisciplinary approaches may proffer insights into the mechanisms that "turn on" genes that may serve a protective function for individuals experiencing significant adversity.

Utilizing animal models of learning and gene expression, several studies have begun to show a direct link between the gene expression process and structural changes in the brain that result from learning. For example, Post et al. (1998) found higher levels of mRNA and nerve growth factor (NGF) in the visual cortex and hippocampus of rats exposed to an enriched environment for 30 days, ev-

idence that a gene transcription process was occurring. Training on a passive avoidance task resulted in significant elevation of *c-fos* mRNA levels in the chick forebrain. A gene expression transcription factor (Anokhin, Mileusnic, Shamakina, & Rose, 1991) and *C-fos* induction also has been found in the rat brain after shuttle-box training (Maleeva, Ivolgina, Anokhin, & Limborskaya, 1989), as well as in Purkinje cells in the cerebellar paramedian lobule following training of rats in a reaching task (Alcantra et al., 1991). Also, the transcription factor *zif-268* has been found in the visual cortex of rats only 4 days after being placed in an enriched environment (Wallace, Withers, Weiler, & Greenough, 1991).

Thus, at the level of learning and cognition, gene expression and the subsequent cascade of processes that eventuate in structural changes in neural substrate may be one process that could be examined as a correlate of resilience. Gene expression in learning, which comes about as a result of transactions with the environment, is perhaps the foundation upon which positive adaptation to adversity is built. In addition, this multilevel perspective, showing linkages among gene expression, neurochemistry, neuroanatomy, and experiences in the environment, again points to the importance of a multiple-levels-of-analysis approach to the study of resilience.

Other work in the area of gene expression has demonstrated the relation of this process to the development of psychopathology in humans. For example, changes in gene expression due to environmental adversities have been implicated in the development of affective disorders (e.g., Post et al., 1994; Post et al., 2003). Similar to the evocation of gene expression through interaction with the environment in animal models of learning, Post et al. (1994) hypothesized that acute events in the environment can have a permanent impact on gene expression, thus accounting for long-lasting changes in subsequent behavioral responses to stressors in the environment. Thus, the interplay of early experience and gene expression processes can potentially lead to vulnerability, depression, posttraumatic stress disorder, and other disorders possibly rooted in changes in gene expression (e.g., Schizophrenia; Post et al., 1994). This formulation, a model based on electrophysiological kindling and behavioral sensitization to psychomotor stimulants and stress, emphasizes an active and dynamic process of transactions between genetic vulnerabilities and experientially mediated effects on gene expression over the entire life span. Also, Post et al. (2003) have theorized that, in addition to pathological changes in gene expression that eventuate in affective disorders, there may in fact be

changes in gene expression that are adaptive and possibly serve as endogenous antidepressant mechanisms. Post et al. (2003) suggest that the proportion of pathological and adaptive changes in gene expression may be a key determining factor in an individual's propensity to have recurring episodes of affective disorder. Likewise, individuals classified as resilient may be found to have a higher proportion of adaptive gene expression processes, allowing them to maintain positive behavioral adaptation in spite of adversity (see also Cicchetti, 2003).

Very recently, molecular genetic methods have been utilized to examine the role that genetic factors, in interaction with social experience, might play in the epigenesis of maladaptive behavior. In a large, longitudinal birth cohort of male children who were studied from birth to adulthood, the investigators sought to determine why some maltreated children grow up to develop antisocial behavior where other maltreated children do not (Caspi et al., 2002). It was discovered that a functional polymorphism in the gene-encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) moderated the effect of maltreatment. Polymorphisms are common variations that occur in the sequence of DNA among individuals. Specifically, a polymorphism is a gene that exists in more than one version (or allele), and where the rare form of the allele occurs in greater than 2% of the population. Caspi and colleagues (2002) found that the effect of child maltreatment on antisocial behavior was far less among males with high MAOA activity than among those with low MAOA activity. The investigators interpreted their findings as providing evidence that a functional polymorphism in the MAOA gene moderates the impact of early child abuse and neglect on the development of male antisocial behavior (Caspi et al., 2002).

Of relevance to research on resilience, it is conceivable that the gene for high MAOA activity may serve a protective function against the development of antisocial behavior in maltreated children (Cicchetti & Blender, 2004). Maltreated children grow up in highly stressful environments. The results of the Caspi et al. (2002) investigation suggest that some maltreated children, but not others, develop antisocial behavior via the effect that neurotransmitter system development exerts on stressful experiences. Specifically, the probability that child maltreatment will eventuate in adult violence is greatly increased among children whose MAOA is not sufficient to render maltreatment-induced changes in neurotransmitter systems inactive (Caspi et al., 2002). Thus, a gene x environment interaction appears to determine which maltreated children will, and will not, de-

velop antisocial behavior. These findings are compelling and this investigation is one of the first studies to document a genetic contribution to resilience in humans. We urge researchers to conduct additional molecular genetic studies with other samples of humans who experience similar and different types of significant adversity in order to ascertain the mechanisms underlying resilient adaptation.

CONCLUSION AND FUTURE DIRECTIONS

Although many questions remain unanswered, a great deal of progress has been made in our understanding of the construct of resilience (Luthar, 2003; Luthar et al., 2000; Masten, 2001). Much of the research focused on elucidating the correlates of, and contributors to, resilient functioning has utilized child, family, and contextual assessments (Luthar, 2003; Luthar et al., 2000). We have emphasized that the time has come to incorporate biological measures into research programs examining the determinants of resilient adaptation. We also assert that the inclusion of biological measures into the psychological research armamentaria currently employed in resilience research, as well as in resilience-promoting interventions, results in a more precise understanding of the mediators and moderators underlying resilience.

Now that the theories and neuroscience techniques are available, and since our understanding of brain development and functioning in both normality and psychopathology has grown, it seems necessary to inquire as to why there has been no research to date conducted on the biological correlates of, and contributors to, resilient adaptation. One impediment to the incorporation of biology into the field of resilience research is that most investigators who examine pathways to resilient functioning have not been trained in the various neuroscience approaches (e.g., molecular genetics, neuroimaging, psychophysiology, neuroendocrinology, immunology). Regardless, this state of affairs can be modified through a number of avenues, including: (1) changing existing training programs and philosophies for graduate and medical students; (2) fostering interdisciplinary and multidisciplinary collaborations; and (3) providing incentives and opportunities for faculty to acquire knowledge and expertise in one or more new scientific areas.

Perhaps an even larger reason for the absence of biological variables in research on resilient functioning is that evidence for the role of biology in resilience could be interpreted as representing a personal attribute of the individual

and that if only the individual had this biological characteristic, then he or she could have withstood the adversities to which the individual was exposed. In essence, the individual could be blamed for not possessing the needed characteristics to function resiliently.

However, as the theoretical underpinnings of research in developmental psychopathology, dynamic developmental systems theory, and developmental neuroscience illustrate, the belief that the identification of a biological factor would inevitably result in resilience (or maladaptation for that matter) is fallacious. Our viewpoint does not reduce resilience to biology, let alone to a unitary biological variable. A multiple-levels-of-analysis perspective to resilience should not be misinterpreted as equating resilience with biology. Moreover, the inclusion of a biological perspective in resilience research should not hearken scientists back to the time when some espoused the view that there were “invulnerable” children.

To the contrary, existing theories in developmental neuroscience are very compatible with organizational and systems theories in the fields of developmental psychology and psychopathology (see Cicchetti & Cannon, 1999a, 1999b; Cicchetti & Walker, 2001, 2003). The incorporation of a biological perspective into research on resilience still requires adherence to a dynamic, transactional view that respects the importance of context. Omitting biology from the resilience equation is tantamount to omitting psychology. Biological and psychological domains are both essential to include in basic research on resilience and in resilience-promoting interventions. If we are to grasp the true complexity of the concept of resilience, then we must investigate it with a commensurate level of complexity.

Regardless of whether it may be a normal or abnormal neural system, building a brain is a dynamic, self-organizing, genetic and epigenetic, multilevel process that unfolds from the prenatal period throughout adulthood. We think that it has become essential for investigators in the disciplines of developmental neuroscience and developmental psychopathology to carry out prospective longitudinal studies that examine the same individuals over developmental time utilizing a multiple-levels-of-analysis perspective. Research also must be conducted to elucidate the similarities and differences in the fundamental neural mechanisms involved in the development of various mental disorders. Furthermore, additional molecular biological investigations on the structure and function of genes and protein involved in neural proliferation, migration, and differentiations must be implemented (Nowakowski & Hayes, 1999).

Moreover, it is important that investigations with human participants be undertaken to ascertain whether, and if so, how, specific environmental occurrences, such as the presence of serious psychopathology in caregivers, child maltreatment, repeated foster care placement, residing in an orphanage, and/or having a mental disorder, selectively exert a deleterious impact on the development of children’s various neurobiological systems as a function of the timing and duration of exposure to these adverse experiences (Cicchetti, 2002; Dawson, Ashman, & Carver, 2000; Gunnar et al., 2001; Parker & Nelson, 2005a). In a related vein, investigations must be conducted to discover what, if any, particular aspects of parenting foster optimal brain development and function in children (Bruer, 1999; Nelson, 2000b).

Now that it is evident that experience can impact the microstructure and biochemistry of the brain, a vital role for very early and continuing neural plasticity throughout epigenesis in contributing to the development of, and recovery from, various forms of maladaptation and psychopathology is suggested. Research has revealed that some early lesions may not be easily reversible, despite the historically prevalent belief that brain insults occurring near the beginning of development were most amenable to reorganization and repair. Conversely, contemporary neurobiological research suggests that in some domains (e.g., sensory, motor, cognitive, memory, and linguistic) and in some areas of the brain, plasticity is possible, including new neuron generation, well into adulthood (Cicchetti & Tucker, 1994a, 1994b; Nelson, 2000a). Moreover, future research must be conducted to examine the limits of plasticity in the social and emotional domains (see Davidson, 2000; Davidson, Jackson, & Kalin, 2000, for evidence of neural plasticity in the central circuitry of emotion). It also is essential to discover the mechanisms whereby latent progenitor cells are controlled and glial cell activation is modulated, in order to elucidate the bases of the brain’s self-repair processes across various neurobiological systems (Lowenstein & Parent, 1999). If scientists can discover the mechanisms underlying the neural plasticity of the circuits of specific domains in individuals with various high-risk conditions and mental disorders, then such information should provide crucial insights for prevention and intervention efforts.

In this regard, prevention research can be conceptualized as true experiments in altering the course of development, thereby providing insight into the etiology and pathogenesis of disordered outcomes (Cicchetti & Hinshaw, 2002). Relatedly, the time has come increasingly to conduct interventions that not only assess behavioral

changes, but also ascertain whether abnormal neurobiological structures, functions, and organizations are modifiable or are refractory to intervention (Cicchetti, 1996). There is growing evidence that successful intervention modifies not only maladaptive behavior but also the cellular and physiological correlates of behavior (Kandel, 1979, 1998, 1999).

Unlike the belief espoused by Huttenlocher (1984) that “intervention programs, to be effective, would have to be implemented during [the] early prenatal period, and certainly prior to school age, by which time synaptic and neuronal plasticity appears to be greatly diminished, if not totally lost” (p. 495), recent demonstrations of plasticity across an array of developmental systems suggest that interventions have promise to exert ameliorative effects long beyond the early years of life (Bruer, 1999; Nelson, 2000b). A major implication of a dynamic developmental systems approach is that the implementation of intervention closely following the experience of trauma or an episode of mental illness should ameliorate the intensity and severity of the response to the illness, as well as the illness course (Toth & Cicchetti, 1999). Such interventions that are closely timed to trauma and disorder onset also should decrease the probability of developing, in a use-dependent fashion, sensitized neural systems that may cascade across development (Post et al., 1998).

As Nelson (2000b) has articulated, “the efficacy of any given intervention will depend on the capacity of the nervous system (at the cellular, metabolic, or anatomic levels) to be modified by experience” (p. 204). Likewise, Nowakowski (1987) asserted that “in order to understand how a modification in a developmental process exerts its influences, it is essential to know where the developmental process is being modified, how the structure of the mature brain will be changed, and how the structural changes that are produced will change the ability of the brain to process the information it confronts during a complex behavioral task” (pp. 568–569). Successful psychotherapy, behavioral therapy, or pharmacotherapy should change behavior and physiology by producing alterations in gene expression (transcription) that produce new structural changes in the brain (Kandel, 1979, 1999). For example, as discussed earlier, stress has been demonstrated to suppress the birth of new neurons in adulthood (see also Sapolsky, 2000a, 2000b), and serotonin has been shown to enhance the rate of neurogenesis in the dentate gyrus. Extrapolating from these findings, Jacobs and colleagues (2000) hypothesized that stress-induced decreases in dentate gyrus neurogenesis play an important causal role in precipitating episodes of major depressive disorder. Reciprocally, pharmacothera-

peutic interventions for depression that increase the neurotransmission of serotonin work at least partly through their role in augmenting the birth of new neurons in the dentate gyrus, thereby contributing to the recovery from episodes of clinical depression.

A number of antidepressants have been shown to increase adult neurogenesis in the hippocampus. Santarelli and colleagues (2003) conducted a study to ascertain the functional significance of this phenomenon. These investigators demonstrated that the disruption of antidepressant-induced neurogenesis in serotonin 1A receptor null mice also blocked their behavioral responses to fluoxetine, a selective serotonin reuptake inhibitor. The results of the Santarelli et al. (2003) investigation provide suggestive evidence that the behavioral effects of antidepressant drugs may be mediated by the stimulation of neurogenesis in the hippocampus.

A substantial amount of research literature suggests that not all individuals who have similar vulnerabilities and who have been exposed to similar adverse experiences develop in a similar fashion (Luthar, 2003; Luthar et al., 2000; Masten, 2001). For example, although child maltreatment can exert a negative impact on the structure, functioning, and organization of the developing brain, it does not appear that the brains of all maltreated children are affected in the same manner. Moreover, because some maltreated children function resiliently despite having been exposed to significant adversity (Cicchetti & Rogosch, 1997; Cicchetti et al., 1993), it is likely that the experience of child abuse and neglect may exert different effects on the neurobiological structure, function, and organization in well-functioning maltreated children than it does in the typical maltreated child. Accordingly, there may be an enhanced neural plasticity in resilient individuals.

Thus, it appears that the impact of life experiences, such as child maltreatment and mental disorder, on brain microstructure and biochemistry may be either pathological or adaptive. In the future, neuroimaging investigations should be conducted in order to discern whether the brain structure, functioning, and organization of individuals who are functioning extremely well despite being exposed to significant adversity and/or having vulnerabilities to mental disorder differ from those individuals with similar experience and/or vulnerabilities who are functioning less adaptively.

Presently, we do not know if the neurobiological difficulties displayed by some persons with mental disorders or individuals who have experienced significant life adversity are irreversible or whether there are particular sensitive periods when it is more likely that neural plasticity will occur.

Moreover, it is not known whether some neural systems may be more plastic than other neural systems or whether there are particular sensitive periods when it is more likely that neural plasticity will occur. Furthermore, it is not known whether particular neural systems may be more refractory to change or have a more time-limited window when neural plasticity can occur. Consequently, it is critical that research investigations on the correlates and determinants of resilient adaptation begin to incorporate neurobiological and molecular genetic methods into their predominantly psychological measurement armamentaria (Curtis & Cicchetti, 2003).

Luthar and Cicchetti (2000) concluded that research on resilience “should target protective and vulnerability forces at multiple levels of influence” (p. 878). The incorporation of a neurobiological framework and the utilization of genetically sensitive designs into interventions seeking to promote resilient functioning or to repair positive adaptation gone awry may contribute to the ability to design individualized interventions that are based on knowledge gleaned from multiple biological and psychological levels of analysis. For example, if an individual has the polymorphism for a gene that is probabilistically associated with a particular negative behavioral outcome and if it is known how this polymorphism affects a specific neurotransmitter system, then psychopharmacological treatment can be initiated (Cicchetti & Blenzer, 2004). Similarly, because stressful experiences can harm the brain (e.g., Bremner, 1999; McEwen & Magarinos, 1997), biological and psychological intervention techniques can be provided to help an individual to better understand and cope with stressful situations. The identification of stress-sensitive neural processes may ultimately provide a basis for the formation of pharmacological and behavioral interventions to ameliorate the deleterious effects of early traumatic experiences (Kaufman et al., 2000; see also Post et al., 2003). Moreover, the inclusion of neurobiological assessments in evaluations of interventions designed to foster resilience enables scientists to discover whether the various components of multifaceted interventions each exert a differential impact on separate brain systems. We think that it is possible to conceptualize successful resilience-promoting interventions as examples of experience-dependent neural plasticity. If assessments of biological systems are routinely incorporated into the measurement batteries employed in resilience-facilitating interventions, then we will be in a position to discover whether the nervous systems have been modified by experience.

Despite the fact that we separately described the biological assessments that we believed would augment our knowl-

edge base in resilience, we advocate that researchers investigating basic processes contributing to resilience and those conducting and evaluating interventions that strive to promote resilience and return function to positive levels of adaptation incorporate a multiple-levels-of-analysis approach (see Cicchetti & Dawson, 2002). Adopting such an approach is essential because, in actuality, biological and psychological systems interact and transact with one another throughout the course of development (Cicchetti & Tucker, 1994a; Gottlieb, 1992).

Furthermore, many of the biological processes that have been discussed in this chapter as possibly being related to resilience are in fact normative processes. For example, neural plasticity is one such process that has clearly been shown to be an inherent property of the central nervous system. This highlights an interesting parallel to a suggestion put forth by Masten (2001), who discusses resilience as an ordinary phenomenon that may mostly come about through the operation of “basic human adaptational systems.” This perspective stresses that, although resilience is a valid, identifiable phenomenon, extraordinary individual qualities may not be necessary in order to overcome adversity. Likewise, at the biological level of analysis, normative processes may mediate resilient outcomes, as long as these systems are functioning within normal parameters. This viewpoint serves to underscore the importance of the interaction of normative systems at all levels of analysis in the promotion of resilience.

Several scholars have contended that the construct of resilience adds nothing to the more general term “positive adjustment” (see review in Luthar, Cicchetti, & Becher, 2000). Because empirical evidence has demonstrated that there are different patterns of positive adjustment that occur with and without adversity and given that there are several studies indicating that the pathways to resilience and positive adaptation may differ, it is indeed likely that positive adaptation and resilience reflect distinct constructs (Luthar et al., 2000). Moreover, the incorporation of biological and genetic measures and methods into research that strives to differentiate between individuals who function well in adversity and those who function well without (or with minimal) adversity may reveal differential neurobiological and genetic correlates of, and contributors to, resilience and positive adaptation, respectively. If distinctions between those two constructs can be made at the neurobiological, molecular genetic, and behavioral levels, then there would be strong evidence for the distinctiveness of positive adaptation and resilience.

In the beginning of the twenty-first century, it is imperative that the field of developmental psychopathology adopts

a multiple-levels-of-analysis approach to the study of both deviant and adaptive functioning. New programs of research must take into account both normal and abnormal developmental processes in examining psychopathology, and intervention studies must be undertaken in order to more fully establish the characteristics of and processes underlying brain-behaviors relations. Most importantly, beyond the calls for research programs incorporating multiple levels of analysis seen in recent overviews of the field (e.g., Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002), such research must actually be supported by funding agencies, many of which still view multiple-levels-of-analysis approaches to research questions as too broad and risky to merit financial support. In addition, journal editors also need to encourage such research by increasing their willingness to publish papers that investigate a phenomenon across multiple levels of analysis, some of which might fall somewhat outside the purview of the particular journal. Furthermore, research in developmental psychopathology that is driven by broadly based theory incorporating multiple levels of analysis must be increasingly encouraged by faculty in the context of graduate training.

In order to ensure that future generations of scholars in developmental psychopathology are exposed to a broad, dynamic, systems-based, multiple-levels-of-analysis perspective, graduate and undergraduate programs in clinical and developmental psychology should encourage students to take courses in a broad spectrum of areas (Cicchetti & Toth, 1991; Pellmar & Eisenberg, 2000). These might include courses on basic neurobiology, neuroendocrinology, and developmental processes, as well as courses that incorporate information on brain-imaging technology, molecular genetic methods, neuroendocrine assay techniques, and other tools involved in assessing neurobiological and genetic processes. Likewise, students in basic science areas, such as neuroscience or molecular genetics, should be encouraged to gain exposure to the fundamentals of basic normative and atypical developmental processes. Further, specific interdisciplinary programs, for both students and faculty, spanning interest areas from clinical intervention to basic neuroscience, would help to foster communication and collaborative research endeavors between the fields of developmental neuroscience and development psychopathology (see, e.g., Cicchetti & Posner, 2005).

Survival depends upon two contrasting phenomena or processes, two ways of achieving adaptive action. Evolution must always, Janus-like, face in two directions: inward toward the developmental regularities and physiology of the living creature and outward toward the vagaries and demands of the environment. These two necessary components of life contrast in interesting ways: the inner development—the embryology or “epigenesis”—is conservative and demands that every new thing shall conform or be compatible with the regularities of the status quo ante. If we think of a natural selection of new features of anatomy or physiology—then it is clear that one side of this selection process will favour those new items which do not upset the old appellation. This is minimal necessary conservatism.

In contrast, the outside world is perpetually changing and becoming ready to receive creatures which have undergone change, almost insisting upon change. No animal or plant can ever be “ready made.” The internal recipe insists upon compatibility but is never sufficient for the development and life of the organism. Always the creature itself must achieve change of its own body. It must acquire certain somatic characteristics by use, by disuse, by habit, by hardship, and by nurture. These “acquired characteristics” must, however, never be passed on to the offspring. They must not be directly incorporated into the DNA. . . . The individual body undergoes adaptive change under external pressure, but natural selection acts upon the gene pool of the population. . . . The acquired characteristics do not become unimportant by not being carried in and passed on by DNA. It is still habits which set the conditions for natural selection. And note this converse principle, that the acquisition of bad habits, at a social level, surely sets the context for selection of ultimately lethal genetic propensities. (G. Bateson, 1979, pp. 234–235)

EPIGENESIS OF BODY AND BRAIN FOR HEALTH IN SOCIABILITY AND LEARNING

In previous publications, we have considered the implications of research on infants’ capacities for communication and their developmental changes for an approach to infant mental health (Trevvarthen, 2001a; Trevvarthen & Aitken, 1994). The powerful innate volitions and emotions of an infant’s Self for engagement with the feelings, interests, and intentions of an Other are adapted to establish affectionate *attachments*. They motivate and regulate collaborative play and learning in relations of *companionship* (Aitken & Trevvarthen, 1997; Trevvarthen, 2005c; Figure 2.1). This interpersonal system requires efficient initiatives from the child to attract and engage with parental responses, and it reacts to the sensitivity and quality of those responses. If the behaviors and expressions of the Other are inattentive, de-

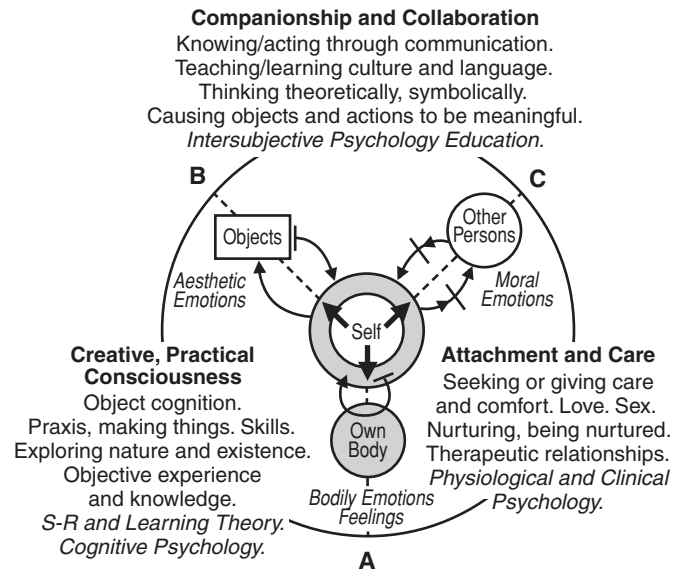

Figure 2.1 Three facets of the active self, for the body (A), for non-living objects (B), and for other subjects or persons (C); and how they are combined in behaviors: of self-protection by attachment to a carer, in private exploration of objects, and when sharing experiences in companionship. *Sources:* From “Intrinsic Motives for Companionship in Understanding: Their Origin, Development and Significance for Infant Mental Health,” by C. Trevvarthen, 2001a, *International Journal of Infant Mental Health*, 22(1–2), pp. 95–131; and “Stepping Away from the Mirror: Pride and Shame in Adventures of Companionship: Reflections on the Nature and Emotional Needs of Infant Intersubjectivity,” by C. Trevvarthen, in *Attachment and Bonding: A New Synthesis* (Dahlem Workshop Report 92), C. S. Carter, L. Ahnert, K. E. Grossman, S. B. Hrdy, M. E. Lamb, S. W. Porges, et al. (Eds.), 2005c, Cambridge, MA: MIT Press.

pressed, or intrusive, or if, in experimental studies, they are briefly made noncontingent on what the infant is doing, this causes the infant to become avoidant, withdrawn, angry, and generally “dysregulated” (Murray & Trevvarthen, 1985; Trevvarthen, 1993a, 1993b, 2005a; Tronick, Als, Adamson, Wise, & Brazelton, 1978).

We believe the evidence shows that a young human person should be understood to require more than external regulation for emotional and autonomic equilibrium or homeostasis, and that already in the first minutes after birth, a baby can demonstrate interest for and awareness of the focused attention of a nearby person and how that person responds to the infant’s expressions of conscious volitions and emotions (Trevvarthen, 2005c). The rhythms of engagement obey rules that prove the movements of infant and adult are generated with matching time (Beebe, Jaffe, Feldstein, Mays, & Alson, 1985; Stern, 1974; Stern, Speiker, & Mackain, 1982; Trevvarthen, 1974, 1986, 1999a). Within a few weeks, in the

“primary intersubjectivity” stage (Trevvarthen, 1979, 1999b; Trevvarthen & Aitken, 2001), this sharing of time sense shows up in imitative mirroring of the forms of expressive movements. It exhibits *attunement* to the affective qualities in expressive movements (Stern, Hofer, Haft, & Dore, 1985), in *felt immediacy* (Bråten, 1988, 1998). It forms turn-taking “protoconversations” (M. C. Bateson, 1975, 1979) that give pleasure to both child and adult over joint coregulated performances lasting tens of seconds (Malloch, 1999; Reddy & Trevvarthen, 2004; Trevvarthen, 1993a, 1999a, 2005a; Trevvarthen & Schögler, 2005).

As their engagements in play develop in early weeks, the mutual regulation between a mother and her infant has measurable properties of what we have described as *communicative musicality* (Malloch, 1999; Trevvarthen & Malloch, 2002). Thereafter, more elaborate games, eventually incorporating orientation to and use of shared things in the nearby world, strengthens the joint awareness, co-consciousness, or what Tronick (2005) calls “dyadic states of consciousness,” and establishes remembered routines of gesture and action and favorite objects and tasks. Mother and baby fabricate expressive “narrations” or “stories of meaning” (Trevvarthen & Schögler, 2005) and build expectations for passing back and forth marked tricks of expression in humorous ways (Reddy, 2003, 2005; Reddy & Morris, 2004). At the end of the 1st year,

the cocreated acts, made meaningful by sharing (Trevvarthen & Hubley, 1978), lead the baby to explore vocal utterances that imitate the words others use to name these “acts of meaning” and their objects (Halliday, 1975; Figure 2.2).

We propose that the infant’s motives and emotions for such a rich evolving experience in approving friendships are capable, if developing abnormally in the child or if not given appropriate support from the human environment, of generating chronic stress and psychopathology that blocks the path to pleasure in human company and the path to meaning (Aitken & Trevvarthen, 1997; Trevvarthen, 2001a; Trevvarthen & Aitken, 2001). The infant’s evident psychic powers are fitted to be regulated in intimate and lively relationships, and they can suffer disorder or trauma from destructive events in these relationships. They are, however, not weak adaptations and are capable of impressive self-corrective reactions to distress. They also respond readily to sensitive forms of therapeutic communication, especially to any improvements in contact and emotionally and practically satisfying engagement with the caregiver (Trevvarthen & Aitken, 2001; Trevvarthen & Malloch, 2000).

Our aim in this chapter is to consider how the vitality and vulnerability of a young human person is adapted to become balanced in relationships—how the stresses and

Figure 2.2 In the first 18 months of life there are marked changes in the infant’s consciousness of other persons and in their motives for communication, before language. Several major transitions can be observed in self-and-other awareness at particular ages. These lead the child toward cooperative interest in actions and objects, and cultural learning. *Sources:* From “The Neurobiology of Early Communication: Intersubjective Regulations in Human Brain Development” (pp. 841–882), by C. Trevvarthen, in *Handbook on Brain and Behavior in Human Development*, A. F. Kalverboer and A. Gramsbergen (Eds.), 2001b, Dordrecht, The Netherlands: Kluwer Academic; “Infant Intersubjectivity: Research, Theory, and Clinical Applications—Annual Research Review,” by C. Trevvarthen and K. J. Aitken, 2001, *Journal of Child Psychology, Psychiatry and Allied Disciplines*, 42, pp. 13–48; and “Regulation of Brain Development and Age-Related Changes in Infants’ Motives: The Developmental Function of Regressive Periods” (pp. 107–184), by C. Trevvarthen and K. J. Aitken, in *Regression Periods in Human Infancy*, M. Heimann (Ed.), 2003, Mahwah, NJ: Erlbaum.

energy costs as well as the gains and opportunities of life are regulated in the first particularly active period of development. From the beginning of an individual human life, the power of action and range of understanding are repeatedly transformed from within the child's brain and body and through engagement with a responsive human environment (Trevvarthen & Aitken, 2003). Each change brings new needs for the energy of adventurous action to be balanced against nurturant care. Failure in these regulations at any stage can bring stressful and unhappy consequences (Cicchetti, 1993; Cicchetti & Cannon, 1999; Korte, Koolhaas, Wingfield, & McEwen, 2005).

We start at the beginning, with conception. A human life begins as one cell resulting from intensely emotional behavior of a man and a woman, who bring the feelings and regulations of their bodies together. This act, which involves collaborative actions of a male and a female body, and of a sperm, the woman's body, and an egg, can create a new and lasting commitment between those adults as affectionate parents of the child, two different persons who are motivated to share the future life of that child and its joys and problems. To understand this emotional commitment, and the child's active responses to it, we must explore the processes of human sympathy that build functional bridges between the processes and motives in different bodies at many levels of organization, from the cellular and anatomical to the intuitively psychological and the consciously contrived (Cicchetti & Dawson, 2002).

We summarize developmental changes in the embryo, observing the cooperative interdependency of cells during pattern formation of tissues and morphogenesis of organs in the body and brain. We follow the growing activity and awareness of the fetus in intimate vital contact with the mother's body, communicating with her in adaptive ways. Then we observe the changing motives in attachments and companionship of infancy in the family, to the beginning of language.

The inquisitive sociability of the child also brings engagements with an increasing range of persons beyond the family. Soon it is prompting the infant and toddler to learn the historical social system of meanings that governs life in community. The child is becoming more involved, by its own activity, in soliciting both biological and physiological partnerships and in discovering behavioral or psychological two-way friendships—frontiers of communication and learning in which purposes, experiences, and feelings are shared or emotional constraints on intimacy are set up. At every stage there are new opportunities and risks, new openings and new barriers (Figure 2.3).

We discover a history of mutual regulations within and between bodies and a kind of engagement of motives and emotions, of neurochemical, hormonal, and behavioral adjustments, that has evident human features from midconception, all of which may be viewed as adaptations for cooperative cultural life. An infant is an animal being evolved to become part of a universe that has been shaped by the thoughts, actions, beliefs, and moral attitudes of past generations of human adults and children, and his or her fate depends on the ways the society of adults manages life and work in the whole community, with its language, technology, and many conventions of belief and social conduct (McEwen, 2001). The causes of child psychopathology, and their potential for creating suffering in adult life, cannot be understood without relating them, not just to the regulations or disorders of the child as an individual organism, but also to his or her impulses as a person who wishes to share the emotions and practicalities of life intimately with other persons (Cicchetti, 2002; Trevvarthen, 2004b).

THE IMPORTANCE OF THE CHILD'S VOLITION IN HUMAN COMPANY

In contrast to the customary emphasis in current behavioral science on the uptake, processing, and retention of forms of information for intelligence of the individual—in cognitive psychology, cognitive neuropsychology, and developmental cognitive neuroscience—we place emphasis on the anticipatory and adaptive *volitional agency* of the child (von Hofsten, 2004), the autopoietic (self-making) vital activities of the human body and especially the *motives and emotions* of the young brain that *cause and evaluate* actions and impel conscious experience and that seek human company (Cicchetti & Rogosch, 1997; Cicchetti & Tucker, 1994; Trevvarthen, 1993a, 1993b, 1997). We give a fundamental causal role to *the emotional qualities in movements* that become socially necessary expressions of how motive impulses change in relation to experience and how they regulate how the child moves in contractual engagements with other persons and their motives (Trevvarthen, 1998b, 2005a). We take the *prospective control of brain-generated movement* (Jeannerod, 1999; Lee, 2004), along with subtle manifestations of physiological regulations that are made apparent to the senses of other persons, to be the source of awareness and of learning about the human world. This leads to a conception of the development of the infant's awareness that differs from the constructivist theory of Piaget (1954), who, though he sought to emphasize the role of the child's actions in con-

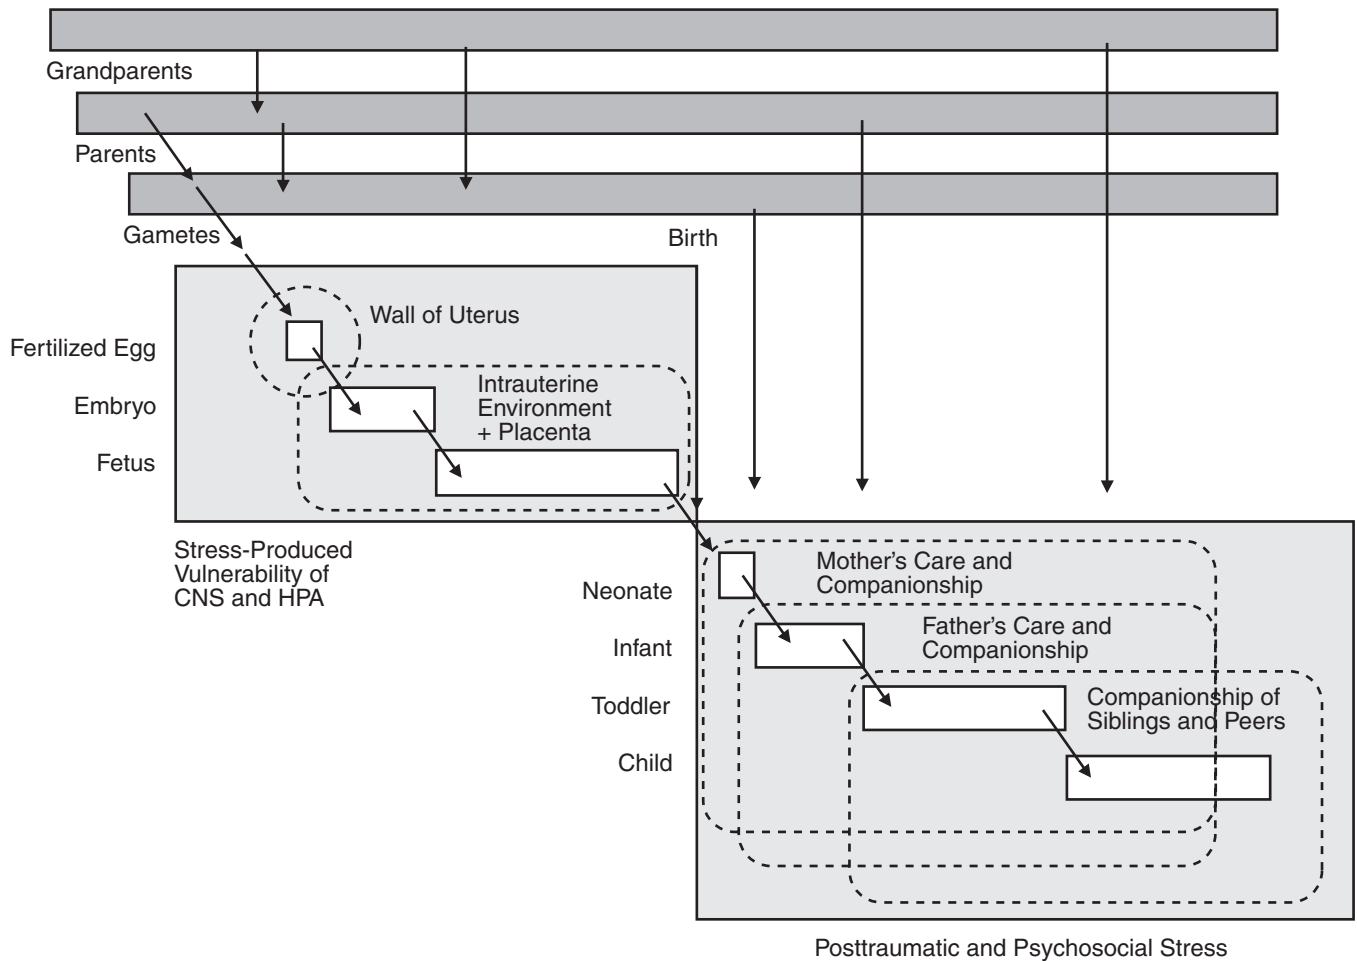

Figure 2.3 As a fertilized human egg develops into a child, it passes through different environments to which it must be adapted, first within the mother's body, then in parental care, and eventually in an increasingly wide companionship of parents, siblings, other family, and the wider society. In each environment the vitality of the child is dependent on regulations across a succession of "frontiers" with the human world, first physiological or *amphoteronomic*, then by the special direct psychological communications which we define as *synrhythmic*, and finally by sharing symbolic awareness of culture and language.

structuring experience, described the infant's sensorimotor initiatives leading to imitative tracking or "accommodation" in response to unexpected present events, and to playful "assimilation" of previously mastered phenomena onto cognitive "schemas" or conceptual models of them as objects of particular future actions. This epistemological approach, to explain the genesis of knowledge, sees emotions as "mere energetics" and does not recognize the potentiality of the emotional qualities in rhythmic expressions of volition for *intersubjective sympathy of purposes*.

We propose that the development of prospective control of moving is the generator of imagination, thinking, and event-mastering "personal narrative" in music and language (Trevarthen & Schögler, 2005) and that a regeneration of motor impulses or "images of acting" prompts retrospec-

tive, imaginative awareness and the formation of memories. And all generative motor processes are coupled with and regulated by emotions that express and assess the potential risks and benefits of the actions to be executed. Motor impulses and emotions are, from the start, shared between the child and other persons (Trevarthen, 1986). They share one another's experience of action. It follows that, if there has been dysregulation by stress or trauma, all recovery of well-being in the face of acquired psychopathology involves recruitment or reactivation of these motive processes and their emotional regulations in communication. It must start with sensitivity by others for the child's volitions.

We see the growing brain as mediating *intentionally* between the vital self-sustaining needs of the child's active body and the material objects and events of the world, and

therefore that the emotional systems of the central nervous system (CNS) are not only responsible for the development of *attachments* to persons who minister to the bodily needs of the infant, but also for the intense intersubjective engagements of *companionship* that make human collaborative life and the transmission of meanings possible (Trevvarthen, 2001b, 2004a; Figure 2.1).

In the embryo, homeotic gene complexes, which help link genetic science to the older science of embryology (E. B. Lewis, 1994) and which are challenging theories of evolutionary change (Robert, 2001), pattern cell differentiation and tissue formation in the emerging central nervous system and impress them with the same map of morphological bisymmetry, polarity, and segmentation as for the rest of the body, anticipating the ways the body will move (Chisaka, Musci, & Capecchi, 1992; Trevvarthen, 1985; Trevvarthen & Aitken, 1994). These gene complexes also appear to determine the way new tissues are added to the cerebral cortex in mammalian evolution (Rakic, 1991). A division between sensory and motor parts is established, and a visceral nervous systems is defined that is adapted to ensure metabolic health of the “internal environment” of the body. The brain develops integrative cell networks that are adapted to become regulators of the behavioral activities of the whole individual self, and it couples with circulatory, digestive, and hormonal systems that mediate in the balance between energy-expending action, conservative and self-nurturing processes, and stress control.

As has been indicated, we are particularly concerned not to regard the interpersonal competence of the child, which is so important in preserving his or her well-being and in supporting vitality of action, experience and learning, as just the product of an acquired intelligent “social cognition” or as a consequence of the impressing of rational rules for life and control of emotions from the adult to the child. Viewing human cooperative life from the adult position, one can be led to assume that rational and linguistically mediated thought and communication must “construct” the child’s capacities to understand or theorize about what others know and do. Research with infants has proved the inadequacy of this position (Reddy & Morris, 2004). There is a primary adaptive process of sympathetic mirroring that engages motives between the brains of any species of animal that lives in societies, and this sympathetic sociability defies reduction to a cognitive information-processing system with plastic learning capacities. Human intersubjective awareness and understanding are founded on detection of an exceptional fluency of temporospatial features of body movement between individu-

als, and infants are born with the required sensory, motor, and integrative functions to participate in this (Trevvarthen, 1986, 2001b).

Understanding human *sympathy of motives* requires recognition of the importance of the innate parameters of central neural action that regulate the periodicity and intensity of integrated body movements (Trevvarthen, 1999a) and that generate the prospective function of the whole “self as agent” who, with specialized sensory capacities, picks up information as perceptual “affordances” to guide, check, and correct movements of the body and its parts so they will, as one integrated system, attain their intended goals effectively and efficiently. We import a new term from Greek, *synrhythmis*, to signify the process, and we describe the motoric engagement between subjects as *synrhythmia*. Sympathy in motives and emotions is made possible by the coalescence of their regularities or rhythms, implied by this term, which means “mutual regulation.” Tronick (2005) describes the awareness part of this mutual regulation as “dyadic states of consciousness.”

With regard to the regulation of the vital economy of the child’s body, to withstand or benefit from moderate stress or exercise and to resist the damage of excessive stress or trauma, we also need a new term in addition to the traditional *autonomics* that defines regulation of the physiological state *of the individual by the individual*, to distinguish not self-regulation, but the *mutual regulation between individuals*, to define the intimate engagement with motives and emotional signals between the child and another who is acting in ways that may affect the child’s life processes in beneficial or damaging ways. The term we introduce is *amphoteronomics*, to signify “ruling together” *in a two-way relationship* or “containment.” This is the process of physiological coupling, or “dyadic regulation of psychobiological states” (Tronick, 2005), that causes the goals and processes of regulation and stress to be shared and, in the beneficial case, leads to a more effective autonomic state or “allostatic balance” (McEwen, 1999) in the child, with likely benefits to the emotional health of the caregiver as well. *Allostasis* describes the dynamic adaptive changes in behavior and autonomic state that reset the goals for stress management (McEwen & Stellar, 1993). Innate adaptation to seek amphoteronomic care, we must not forget, leaves the child open to damage by neglect or abuse if the adult is incompetent to respond helpfully.

There is growing evidence that early life experiences in stressful parental care, of neglect, intrusiveness, and physical abuse, can have a lasting influence, increasing “allostatic load” throughout life and predisposing affected adults to a variety of emotional disorders, such as depression,

anxiety, hostility, suicidal feelings, and substance abuse (McEwen, 2001, 2003). It is not just the pain of abuse or severe punishment that causes ill effects, but the learned anticipations of stress, which activate autonomic defenses, precipitating effects that may leave functional disorder in many regulatory systems of the brain, changing motives and awareness.

In our consideration of the situations and factors that predispose a child to psychopathology, we seek to understand what every child needs, what the universal requirements are for well-being in childhood relationships, but we must also allow for the changing needs of different ages and of different individuals whose epigenesis or constitutional adaptations may predispose them to different ways of acting, communicating, and learning. Individual differences of morphology and character are exceptionally large between human beings, as compared to other species, evidently in adaptation to the many different roles and responsibilities to be taken up by individuals in the elaborately cooperative communities we have to live in. These differences, especially those of personality or character, are not only due to the species-specific differences in genetic constitution of human beings, as study of the intrauterine development and postnatal psychology of homozygotic twins makes clear (Piontelli, 2002). Prenatal experience can leave lasting effects on individuals' emotional life and their dispositions to act, communicate, and learn.

Care and therapy, too, can be interpreted usefully only from an understanding of the nature of intrinsic regulations that assist development of a child at a given stage toward new awareness and skills, and to a different state of vital well-being, in the care and companionship of family and friends. In this intricate process of change in biological organization, genes are just one kind of player.

As Gregory Bateson (1979, see chapter epigraph) explains, survival depends on a two-way epigenetic negotiation with the environment, but it is "the developmental regularities and physiology of the living creature" that set the project. "Always the creature itself must achieve change of its own body. It must acquire certain somatic characteristics by use, by disuse, by habit, by hardship, and by nurture" (G. Bateson, 1979, p. 235).

REGULATION: BALANCING THE ENERGY BUDGET OF THE BODY IN ACTION

Life is work. A moving animal expends energy and must recuperate and hoard it (Schrödinger, 1944). As animals

have evolved large multicellular bodies they have developed adaptations for survival in ecological communities of many species, and in societies where they collaborate and compete with members of their own species. The regulation of their life becomes more dependent on psychological appraisal of their own activities, on learned understanding of how to use the resources of the environment to benefit their well-being, and how this intelligence may be communicated.

Life on Different Scales, from the Single Cell to Society and the Global Culture

Even a *single-celled organism* requires adaptive processes that select resources, that are "environment-expectant" on the molecular level, and that place the cell advantageously within the motions and changes of composition or physical state of the media in which the cell lives. The cell has a surface with complex macromolecular structure that functions as a barrier and selective transport system. Its internal substance or cytoplasm contains other macromolecular structures, such as energy-producing mitochondria and protein-synthesizing Golgi bodies, each with a surface across which internal energy and material transactions are controlled. The nucleus is just one vital compartment with a surface membrane that mediates exchanges to and from the cytoplasm. This cell system is the minimal dynamic unit of any life form.

The cell as a living unit maintained by macromolecular processes has limited size, typically about 10 to 20 μm , which restricts the power of its action and its mobility. These limits are overcome by cells coalescing in *multicell organisms*, in which life functions are distributed in specialized cell groups or organs that collaborate and sum their actions. Multicellular organisms, built by a complex pattern of division, differentiation, and migratory arrangement of cells that start with the same complement of genes, exhibit distribution of work between cells and have a body form adapted to house that cooperation. In the process of cell multiplication, the actions of genes are changed by transforming their structure and especially by regulating their transcription through engagement with activating and repressing factors.

Cells reproduce by division. The linear sequence of chromosomal DNA molecules in the nucleus is replicated and, in principle, the genetic structure is allocated in equal measure to the single nuclei in each new cell. Genes confer one key source of continuity of vital adaptive structures and processes from each cell generation to the next, and

from parent to offspring, but they are not the only one. There is also, from the beginning, transmission of adaptive elements through the cytoplasm and cell membrane, which is also reproduced as cells divide.

Asymmetric division, generating cell differences, is apparent in the first cell division of the fertilized zygote (Schneider & Bowerman, 2003). In the cell division cycle of a vertebrate brain, there are reciprocal interactions among genes, gene products, and molecules that regulate the expression or suppression of future gene transcription (Cayoteet & Raff, 2002; Roegiers & Jan, 2004). There are also mechanisms for the transformation of gene action in reaction to stimuli from the environment of the cell, such as in the case of dorsoventral positional information in the developing neural tube provided by graded Sonic hedgehog (SHH) molecules and then interpreted by transcription factors (Kobernick & Pierler, 2002). Sexual reproduction ensures that genetic material from different cells is combined to create new variants of cell activity that may have adaptive advantage in relation to a varying environment.

The cells, as they segregate and adhere in selective assemblies, develop different roles in collective action, generating morphogenesis of the body and its organs (Edelman, 1988), transforming the power of the organism to use the environment with benefit. There are cells, tissues, and organs that mediate in relations of the whole organism and the environment (nervous system), others that regulate the balance of functions between vital metabolic processes and action of the whole (endocrine system), and still others that retain a capacity for reproduction of that life form by production of gamete cells (sexual system).

Mobile animals have a body form adapted to move in service of a set of vital functions: They exhibit *locomotion* to search out conditions for well-being in a supportive environment and to move from potentially harmful places; they make movements of *orientation*, focusing receptors to select sensory information to guide their actions; they carry out acts of *consummation* to discover and assimilate resources for respiration and digestion, movements to eliminate waste products; and they transfer sex cells for *reproduction*. They have nervous systems that integrate action of different muscles, both visceral and somatic, to serve all these purposes.

Social animals sense one another's internal states through external changes in appearance of the body and from the quality or expression of movements made to regulate vital activities. They form communities in which individuals assume complementary roles that are adapted to benefit the group; they move together in migrations and systematic relationship to the geography of their habitat, learning and passing on habits that regulate the time and

extent of movements; and they collaborate in foraging, in mating and sexual activity, and in the care of offspring.

The whole range of these behaviors, from cells to societies, participates in regulatory processes to protect, sustain, and vary the life activities of an animal species. The integration of processes in each body is mediated by circulatory and neural systems that are adapted to transport or transmit hormones, growth substances, and neurotransmitters that raise or lower the activities of receptive tissues and organs. Internal regulation between cells, between tissues, and between physiological systems shares functions with the interpersonal regulation we experience in our growth and development and in everyday life.

Autonomic, Neurohumoral, and Immunological Protection of Vital State

Regulation of living concerns the whole moving animal, integrating muscular action patterns of all body parts in concert. These patterns are initiated by "motor images" synthesized in widespread neuronal assemblies, with prospective reception of sensory information about environmental resources and affordances (Bernstein, 1967; Jeannerod, 1994). The CNS is organized to couple visceral and somatic processes and is transformed during development to increase the efficiency of the process.

The *autonomic nervous system* (ANS; Langley, 1921) consists of peripheral nerves and ganglia connected to regulatory systems of the brain stem and spinal cord that control smooth muscles and glands of the viscera. It originates in the embryo from neural crest cells that migrate from the margin of the neurectoderm to form a variety of cell types (including sense organ primordia, bipolar neurons of the dorsal sensory ganglia, sympathetic neurons, and the precursor of the adrenal gland) that become important in mediating between the environment and internal vital functions.

The ANS is responsible for automatically maintaining the internal environment by regulating blood chemistry, circulation, respiration, digestion, and the immune system responses (Bernard, 1878; Cannon, 1939). Its visceral motor outflow, divided into the *sympathetic nervous system* (SNS) and the *parasympathetic nervous system* (PNS), both of which innervate smooth muscles throughout the interior of the body and the skeletal muscles of the respiratory system in the diaphragm and chest. Their function is dynamic and adaptable, because the demands of life for a free-moving animal are constantly changing, and the system must be sensitive to plans for motor initiative and perceptuocognitive appraisal of environmental opportunities or threats. CNS structures, including forebrain limbic and

neocortical tissues, are in reciprocal relation with the brain stem and diencephalic nuclei and interneuronal systems that receive input from and send output to the ANS.

The PNS has its central efferent neurons in the intermediolateral (visceral) column at the anterior and posterior ends of the spinal cord. Its function is primarily *trophotropic*, promoting energy uptake (in feeding and respiration), reducing energy expenditure (by vasoconstriction), and preserving energy resources. The principal brain stem nucleus of the *cranial PNS* is the *dorsal motor nucleus of the vagus* (DMX). The second PNS nucleus, the *nucleus ambiguus* (NA), innervates the heart and trachea, as well as skeletal muscles of the upper esophagus and pharynx via the vagus (X) and glossopharyngeal (IX) nerves. The ganglia of the parasympathetic system are in close relation to the peripheral target organs. Its preganglionic and postganglionic axons employ acetylcholine (ACh) via nicotinic receptors for the former and muscarinic receptors for the latter. Peripheral ANS action has complex variants of neurotransmitter, neuromodulation, and neurohumoral interactions.

The genital and urinary viscera are controlled by the *sacral PNS*, which originates in cell bodies in the posterior spinal cord and are located in the intermediolateral cell column of second, third, and fourth sacral segments. These neurons send preganglionic nerve fibers via the pelvic nerve to ganglia located close to or within the pelvic viscera. Postganglionic fibers are relatively short and supply cholinergic terminals to structures involved in excretory (bladder and bowel) and reproductive (fallopian tubes and uterus, prostate, seminal vesicles, vas deferens, and erectile tissue) functions.

The output to the SNS originates from the intermediolateral (visceral) thoracic and lumbar spinal cord, which connects by ACh synapses to sympathetic chain ganglia and thence to visceral organs in which the synapses are noradrenergic. Its function is *ergotropic*—to mobilize motor activity and its supporting metabolism to meet challenging circumstances—and it depends on expending energy reserves. A major sympathetic output is to the *medulla of the adrenal gland*, exciting its cells to release catecholamines *noradrenaline* (norepinephrine) and *adrenaline* (epinephrine) into the circulatory system and thus to the brain and many other organs. “Autonomic neuroendocrine activation in response to stresses serves to mobilise visceral resources in support of the requirements of ‘fight and flight,’ and of the attentional and cognitive demands of adaptive challenges” (Berntson, Sarter, & Cacioppo, 2003a, p. 306).

The ANS also acts as a sensory system (Dworkin, 2000). Thus, 75% of the nerve fibers in the vagus nerve are afferent, carrying information from dorsal roots of the spinal cord on

the internal state of the body, from baroreceptors responding to changes in blood pressure, from chemoreceptors, and from other interoceptors in various tissues of the body, and these sensory inputs can influence other systems. These sensory afferents terminate in the *nucleus of the tractus solitarius* (NTS) in the brain stem, which is a major relay from visceral nuclei sending input to modulate rostral neural systems that, in turn, project to autonomic nuclei in the brain stem.

Through its connections with the *locus coeruleus* and *raphe nucleus*, the NTS exerts widespread effects in most of the brain by serotonergic, adrenergic, and noradrenergic projections. Baroreceptor input reduces cortical arousal, suppresses spinal reflexes, and attenuates pain (Dworkin, 2000). Vagal projections to the medial reticular formation could be responsible for the effect of vagal nerve stimulation (VNS) on sleep and alertness.

The adrenal gland is the major link between the autonomic and endocrine systems and further expands the response repertoire of both arms of the ANS. The adrenal cortex, which is largely regulated by the *hypothalamic-pituitary-adrenocortical axis* (HPA), and the adrenal medulla, which is primarily under neural control from the SNS, have shared responsibilities in responding to stress and metabolic aberrations. The coordinated response during stress of elevated plasma *cortisol* (from the adrenal cortex) and the catecholamines *norepinephrine* and *epinephrine* (from the adrenal medullary cells) indicate that central limbic and hypothalamic centers exert combined influences to ensure the needed neurohumoral adaptations.

The ultimate integration of autonomic functions and behavior, including learned activities, is coordinated through the hypothalamus and limbic system. The whole motivating mechanism of the brain is implicated. The ANS functions

at the interface of the vegetative and voluntary human life, maintaining and controlling *homeostasis* (stability of the internal environment) and such life and species-sustaining functions as circulation, digestion, excretion and reproduction as well as normal metabolic and endocrine physiology, and the adaptive responses to stress (flight or fight response). . . . In the broadest sense the “central and peripheral” ANS underlies the most complicated of human behavior—energy and excitement, joy and sadness, pleasure and pain; ANS activation, or lack thereof, identifies the significance and quality of behavior. These most human expressions underlie the conduct of human behavior and thus society itself. (Hamil, 2004)

Neurotransmitters in Regulation of Action and Awareness

The central nervous system carries out its integrative and regulatory functions by means of intercellular transmission,

at cell junctions or synapses, of impulses that eventually excite motor activity. The patterning of behavior and its adaptation to what the environment is offering depends on how sensory information is sought for and assimilated for directing movements. Processes of behavioral coordination and attention to the environment are mediated at very different rates, even within the few seconds of immediate conscious engagement with the world—the psychological present. Changes in synaptic function lead to learning and retention of memories and the creation of different motives and emotional evaluations for dealing with experiences.

An important distinction must be made between slower changes of emotional states or interest and level of activity and the extremely rapid whole-brain assimilation of sensory information and the fine coordination of muscular excitations throughout the body in immediate adaptation to the environment (Bradford, 2004; McGeer, Eccles, & McGeer, 1978).

Neurotransmitters are chemicals released in small amounts from a nerve cell when action potentials (nerve impulses) reach a synapse attached to another nerve cell or to a muscle or gland cell (Bradford, 2004; Iversen, 2004; Thompson, 2000). They excite changes in the receptor cell that stimulate action potentials, thus propagating nerve activity, or their effect may be to inhibit cell activation. The excitatory or inhibiting effects of transmitters depend on other factors in the synaptic gap and on the surface state of the receptor cell. Neurons are specialized in their capacities to synthesize, activate, and inactivate transmitters, which are of many types with different functions in the chemical coding of intercellular messages. The efficiency of a transmitter depends on its affinity for a wide range of receptor types on the surface of the receiving cell, which vary in their molecular structure and response to the transmitter.

Until the 1970s, only six types of neurotransmitters were known in the brain: *noradrenaline (NA)*, *dopamine (DA)*, *serotonin or 5-hydroxytryptamine (5HT)*, *gamma-aminobutyric acid (GABA)*, *acetylcholine (ACh)*, and *glutamate (GLU)*. Since then, not only have other types of neurotransmitters been identified, including gases such as *nitrous oxide (NO)*, but also the so-called *neuromodulators*, which modulate the effect of the neurotransmitters.

The main types of neurotransmitters are now classified as follows:

Monoamines (ACh, adenosine, DA, histamine, NA, 5HT). ACh released from motor nerves excites muscle contraction, and it is also released from autonomic nerves to smooth muscle activity and gland secretions. NA mediates in the excitation of smooth muscle, heart muscle, and

glands, often in opposition to ACh. Monoamines are diffuse in their effects and act to modulate the activities of the more precise functions of sensory response and motor activation; that is, they are essential in the motivational and emotional regulation of psychological functions.

Amino acids (aspartate, GABA, glycine, glutamate) performing fast, high-precision chemical signaling in the CNS in volitional and perceptual control of behavior. GABA is inhibitory and serves in focusing neural communication, increasing its differentiation and precision. Glycine is the inhibitor of the spinal cord, regulating reciprocal reflex functions. Glutamate is the main excitatory agent in the CNS, its functions being patterned by a range of transporter factors and many receptor types.

Neuropeptides (mRNA, β -endorphin, cholecystochinin, dynorphin, enkephalins, oxytocin, somatostatin, substance P, neuropeptide Y, vasopressin, and many others). They appear to be modulators concerned more with trophotropic self-regulatory functions of the body, including states of pain and pleasure (Panksepp, 1993).

Neurotransmitters and neuromodulators act on two different kinds of receptors on the surface of postsynaptic cells: ionotropic and metabotropic (Bradford, 2004; Herleinius & Lagercrantz, 2004). The *metabotropic receptors* are G and N proteins in the bilipid layer of the cell membrane, and their effect is slow, lasting tens of milliseconds. They are essential in the preparatory modulation of integrative systems so they can efficiently and selectively respond to the environment with appropriate levels of action. Adrenergic, muscarine, and peptidergic receptors are often metabotropic and play a more modulatory role in the mature CNS.

In contrast, *ionotropic receptors* are part of ion transport gates and act very fast, in less than a millisecond. Acetylcholine, GABA, glycine and serotonin act on ionotropic receptors, and they carry out the instantaneous transactions of sensory motor coordination in the active and prospective control of behavior.

Volitions and Their Effects Mapped in the Brain

All active organisms, growing plants or moving animals, have adaptive processes that formulate viable prospects for their actions. Animals move with short- and long-term *prospective control in space and through time* (Bernstein, 1967; Lee, 1998). Each motor step in space taking a certain time must estimate effects that should follow an event of that duration and in that space, and regulate its expression accordingly. Elaborated sequences of movement must have ways of dealing with eventual risks and benefits at each and

every step along the way, and this regulation requires setting desirable states or goals in advance (Jeannerod, 1999).

Some consequences of acting can be dealt with online by sensory stimulation of immediate adaptive approach or avoidance movements, but in general, the processes of life on the move require an imaginative system that maps out behavior in the future, prospecting ahead in space and time, and that, moreover, is capable of retaining information, in memory, about the consequences of acts made in the past.

A large animal's movements are guided from within a central brain. Even the most elementary neural net of a worm-like creature must represent the relationship between the form changes its output excites in the body by regimented muscular contractions, as well as the effects of stimuli that are detected by the sensory receiving organs, at the interface of the net with the world, or in the body. This relationship is constituted as "experience," which means "from acting": It has a rudimentary self-experience (Merker, 2005; Sperry, 1950; von Holst & Mittelstaedt, 1950).

For larger, more complex and forcefully active animal bodies that challenge the media in which they move in more powerful and risky ways, the anteroposterior polarity, bilateral symmetry, and dorsoventral differentiation of the body form adapted to forward progression must be represented in many systems of the brain, all of which map both the output and the sensory information the moving body will receive, looking ahead to how movements must be coordinated and regulated in consciousness (Bernstein, 1967; Paillard, 1960; Sherrington, 1906). Activation of the interlinked *somatotopic* (body-charting) or *telotopic* (direction-charting) maps of the body in the brain creates a *unified behavior field*, defined by the polarized, bisymmetric, and dorsoventrally differentiated form of the body and how that form may move and turn (Trevvarthen, 1968a, 1968b, 1985; Figure 2.4). All the risks and benefits of acting in and against the outside environmental media or of ingesting components of it must also be regulated by the brain in *motives* that control the

Figure 2.4 Left: The map of the visual field on the midbrain roof (tectum) of vertebrates 'plots' events outside the body in relation to the form of the body and its movements. Objects that attract interest are oriented to, which brings them into the central field, in front of the head, that is into the midline structures of the brain. These are connected to brain structures that evaluate the object, for example identifying it as food. Then "consummatory" behaviours (such as eating), make appropriate use of the object. *Sources:* From "Two Mechanisms of Vision in Primates," by C. Trevvarthen, 1968a, *Psychologische Forschung*, 31, pp. 299–337; and "Vision in Fish: The Origins of the Visual Frame for Action in Vertebrates" (pp. 61–94), by C. Trevvarthen, in *The Central Nervous System and Fish Behaviour*, D. Ingle (Ed.), 1968b, Chicago: University of Chicago Press. Right: A newborn infant, less than 30 minutes old, shows awareness of the changing place of a red ball being moved by a nurse, and the baby orients all parts of the body to the object. This behavior depends upon the precise mapping of the visual "image" in the brain onto the neural maps of motor coordination. Photo by Kevan Bundell.

whole interface between body and environment (Jeanerod, 1994; Trevarthen, 1998b). Consciousness is the function that regulates this motor unity of motivated purpose in a multisensory space (Merker, 2005).

Cerebral Mechanisms of Human Imagination and Memory

In the human case, these preconditions for intelligent nervous control of an active life are set up in the anatomy of an exceptionally large and complex brain by processes of cell multiplication and interneuronal tissue formation that is well advanced in the embryo stage, before there is any nervous excitation of body movement and before any of the sensory systems can transmit their excitation into the brain (Trevarthen, 1985, 2004a).

Long-term behavioral initiatives require the human agent to anticipate dangers to the substance and organization of life that might occur after many intermediate actions have been performed and to plan exploitation

of beneficial encounters with objects and events. This record and program for action requires an exceptionally large cerebral neocortex, which records a “personal narrative history” of the single conscious agent or self, the mobility and sentience of which is unified in subcortical regions (Merker, 2004, 2005; Panksepp, 1998b, 2000; Figure 2.5).

Most of all, human actions are *social*. They require that an individual’s actions engage with, and discover ways of cooperating with, what other individuals do (Decety & Chaminade, 2003; Hari & Nishitani, 2004). For this to succeed, the internal motives that precipitate initiatives in action, and their autonomic regulations, of one have to be detectable to and motivating for the other. This is what is meant by “intersubjective” or “interagentive” engagement: between volitional selves and others (Aitken & Trevarthen, 1997; Trevarthen, 1998a, 1999b; Trevarthen & Aitken, 2001). The regulation of this requires what amounts to a duplication of the self in each individual; this is what Bråten (1998) calls a “virtual other.”

Right: Map indicating the flow of functions between brainstem and the hemispheres and between different regions of the cerebral cortex. Sources: From “The Neurobiology of Early Communication: Intersubjective Regulations in Human Brain Development” (pp. 841–882), by C. Trevarthen, in *Handbook on Brain and Behavior in Human Development*, A. F. Kalverboer and A. Gramsbergen (Eds.), 2001b, Dordrecht, The Netherlands: Kluwer Academic; and “Brain Development” (pp. 116–127), by C. Trevarthen, in *Oxford Companion to the Mind*, second edition, R. L. Gregory (Ed.), 2004a, Oxford, NY: Oxford University Press.

Emotion Expression and Communication of Motives and Thought: The Special Visceral Efferent System of the Parasympathetic Nervous System

The parasympathetic nerves of humans include the *special visceral efferents of the head*, which not only exert immediate dynamic regulation of vital functions of blood circulation, respiration, digestion, and excretion, but also, as an elaboration of a trend seen in other social species, express emotional states in control of intersubjective contacts and relations, that is, in communication with other subjects (Porges, 1997; Table 2.1). All the muscles of human communication, of the *eyes, face and mouth, vocal system, head and neck*, which are constantly active in natural human conversation, and which have disproportionate representation in the sensory and motor maps of the neocortex (Penfield, 1958; Figure 2.6), receive their efferents from the cranial nerves (Aitken & Trevarthen, 1997; Trevarthen, 2001b). In less sociable, primitive animals, these efferents are almost

exclusively concerned with visceral, self-regulatory functions (Table 2.1).

It is of special interest that human *hands*, in addition to their extraordinary dexterity in manipulation, have become associated with the organs of communication as supremely efficient and adaptable organs of communication, capable of conveying sensitive interpersonal feelings by touch and rhythmic caresses as well as of acquiring a language ability equal to that of speech.

We note that infants are born with a capacity to imitate not only the dynamics and expressive forms of vocalizations and facial movements (such as tongue protrusion), but also isolated and apparently arbitrary gestures of the hands (such as index finger extension; Heimann, 1998; Kugiumutzakis, 1998). Neonatal hand movements are investigative, self-stimulatory, and regulative for the infant, as well as communicative, and “neoplay” with touch by the hands appears to build a self-awareness from which an awareness of objects remote from the body may be

TABLE 2.1 Cranial Nerve Nuclei, Special Visceral Sensory and Motor Functions, and Systems for Expression and Receptions of Emotion

Communication Movements	Visceral and Somatic Movements	Cranial Nerves	Visceral and Somatic Senses	Communication Senses
		1 Olfactory	Odor, taste	Smelling/tasting other
		2 Optic	Light sense, vision	Seeing other
Looking at other, directing gaze, pupil changes	Eye rotation, lens and pupil movements	3 Oculomotor	Eye-muscle sense	
Looking at other, directing gaze	Eye rotation	4 Trochlear	Eye-muscle sense	
Face expressions; vocalizing, sucking, kissing	Mastication	5 Trigeminal	Facial feelings	Feeling other's touch, feeling own face
Looking at other, eye expressions, crying	Eye rotation, lifting eyelids, tears	6 Abducent	Eye-muscle sense	
Face expressions, speech; listening to speech	Eating, control of middle ear muscles	7 Facial	Taste; tongue, mouth	Tasting/feeling other
		8 Auditory	hearing, balance	Hearing other, hearing self
Vocalizing, laughing; expression in voice; coughing	Coughing, biting, salivating, swallowing	9 Glossopharyngeal	taste	Tasting/feeling other
Vocal expression; circulatory signs; panting, gasping	Heart and gut activity, vomiting, fainting, breathing	10 Vagus	Taste; heart, lungs, gut	Feeling own emotion
Head expressions; vocalizing; laughing, coughing	Head and shoulder movements, swallowing	11 Accessory		
Vocalizing, speaking; licking, sucking	Tongue movements	12 Hypoglossal

Kirkpatrick (Eds.), 1997, New York: New York Academy of Sciences; and “The Neurobiology of Early Communication: Intersubjective Regulations in Human Brain Development” (pp. 841–882), by C. Trevarthen, in *Handbook on Brain and Behavior in Human Development*, A. F. Kalverboer and A. Gramsbergen (Eds.), 2001b, Dordrecht, The Netherlands: Kluwer Academic.

conceived and their affordances explored (Adamson-Macedo, 1998, 2004). All of the expressive movements of the infant’s voice, face, and hands appear to be adapted for interpersonal transmission of the impulse to know and do in dialogue (Trevarthen, 1986, 2001b, 2004d, 2005c), and all are potent vehicles for transmission of emotions and states of sympathetic motivation.

Homeostasis and Allostasis in the Integration of Autonomic and Emotional Regulations in Engagements with the World and with Society

The ultimate integration of autonomic functions and behavior, including learned activities, is coordinated by the hypothalamus and limbic system. In the broadest sense one can view the limbic system as the cortex of the autonomic nervous system. (Kalia, 2004)

The classical reflex homeostatic model of the ANS is too restrictive and does not reflect the flexible adaptability of autonomic regulation (Berntson, Sarter, & Cacioppo, 2003b). Homeostasis requires anticipatory ANS responses, which can arise by learning, as in the salivary response of dogs trained by Pavlov, in the insulin release of a person an-

ticipating a meal (Dworkin, 2000), in conditioned fear reactions (Ohman, Flykt, & Lundqvist, 2000), and in anxiety states that are characterized by hyperattention to threat-related stimuli (Berntson, Sarter, & Cacioppo, 1998). Stimuli that are both interoceptive (sensed inside the body) and exteroceptive (sensed from the outside world) can control the ANS with anticipation, and this anticipation is changed by learning. The ANS, being in intense reciprocal relationship with many other regions of the brain and in accord with its role as regulator for the whole organism, is coordinated not only with the humoral mechanisms that control visceral functions through its connections with the hypothalamus, but also by way of the forebrain systems that mediate volitional behavior and learning.

Mental (cognitive) imagery can trigger autonomic responses, and human imaginative expectancy is fluent, dynamic, reliant on memory, and, as in dreaming, rich in prospects of dramatic, artistic, and musical experiences or activities and in language, all of which may be coupled with prospective changes in ANS activity. Conversely, somatovisceral feedback may affect cognitive and emotional processes (Berntson et al., 1998). Vagal afferents to the NTS enhance emotional memory in animals (McGaugh,

Roozendall, & Cahill, 2000), and stress hormones affect memory.

The *locus coeruleus* and the *nucleus paragigantocellularis* carry ascending visceral afferents to the basal forebrain cortical cholinergic system and cortex. Autonomic feedback can trigger panic attacks (see Bechara, Damasio, & Damasio, 2000). ACh enhances cortical processing (Sarter & Bruno, 2000) and may produce confused cognitive activity, as in the irrationality and hyperattention of anxiety states.

In the opposite sense, from processes of intentional action and engagement with experience to autonomic state, the medial frontal cortex, especially of the right hemisphere and most conspicuously in early childhood, plays a major role in affect and autonomic control, regulating both positive attachment relations and anxiety reactions (Schoore, 2001a, 2003a). Research with animals has clarified this function. When the inhibitory influence of the ventromedial prefrontal cortex is absent, the instinctive fear response of the amygdala remains unchecked and triggers overwhelming aversive responses. Without prefrontal feedback regarding the level of threat, a rat remains in a maladaptive state of defensive arousal (Morgan & LeDoux, 1995). This may be compared with the speechless fear of Posttraumatic Stress Disorder (PTSD; van der Kolk, 2003).

The adaptive process that actively maintains functional stability through change is defined as *allostasis*: change of internal state set points to meet anticipated adaptive demands, for example, when one has the intention to exercise vigorously or when a threat to survival is expected (McEwen, & Stellar, 1993; McEwen, & Wingfield, 2003). Plans for active behavior include regulation over autonomic states to achieve this flexibility (Berntson & Cacioppo, 2000; McEwen, 1999). Allostasis restores homeostasis or well-being *by adaptive change of motives and regulations for behavior*. It functions to control the balance of effort or energy expenditure against energy and regulatory gains from rest and recuperation. It can incur a cost to the strength and health if regulations demand too much change.

Literally, allostasis means “achieving stability, or homeostasis, through change” (Sterling & Eyer, 1988), and a damaging or weakening response is referred to as allostatic load. Maladaptation to modern urban life, where people have to suppress the flight-fight responses of somatovisceral activation evolved for transient challenges (Dworkin, 2000) while they are subjected to prolonged somatovisceral activation with chronic psychological stresses, may have long-term health costs (McEwen, 1999, 2001).

The Function of Emotions as the Currency of Social Regulation

To understand how the integrated intelligent and passionately felt behavior of the animal can control its engagements with the external world, how it can direct movements to have desired effects, and how it can anticipate or respond to beneficial or stressful outcomes, it is helpful to divide the aims or adaptive functions of behavior into two kinds by adopting and extending the terminology of Hess (1954; Figure 2.7 and Table 2.1), who pioneered intracerebral stimulation studies of innate emotional motor systems in the diencephalon of mammals:

1. Active *ergotropic* or *energy-expending efforts* of the animal engage with the environment and change how the animal's body contacts, receives stimulation from, takes in, and changes external matter, how the matter is used to support the body and allow the animal to move about and steer its progress, and how potentially harmful events or situations are avoided.
2. *Trophotropic* or *energy-obtaining or -conserving states* increase the potential for action, either by storing energy sources from food and oxygen or absorbed heat, by taking in necessary water and nutrients, or by allowing restorative processes such as sleep. This type of restoration can be taken to include learning processes that increase the efficiency and versatility of movements.

Animal action is guided by prospective “plans” that specify environmental benefits or risks and that are selected with reference to expected outcomes of changes in the direction and goals of movement. If these aims and expectations accurately detect and anticipate the changes in contact and relationship to external objects and events consequent on moving, then the movements achieve their purpose. If the anticipations are inaccurate, then behavior may have unwanted consequences.

In the evolution of the vertebrates, a set of structures have evolved in the forebrain that amplify and extend the capacities of the regulatory mechanisms for controlling and expressing internal regulatory processes in movement. These include the *limbic structures* (Swanson, 2004), identified by Broca (1878), Papez (1937), and MacLean (1952, 2004), and extensive structures of the *emotional motor system* throughout the CNS (Holstege, Bandler, & Saper, 1996). Key limbic structures of the cerebral hemispheres identified in modern accounts of the brain mechanisms of emotional regulations

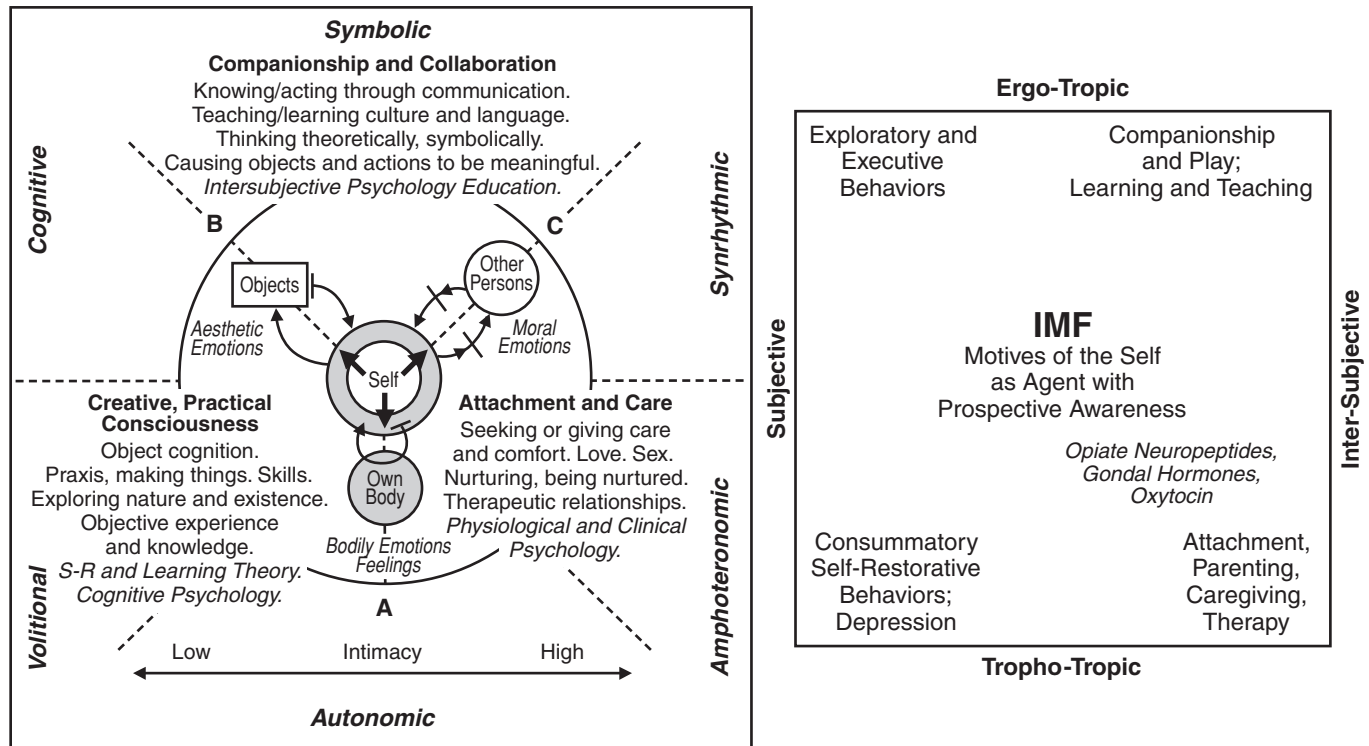

Figure 2.7 Left: Map of the three types of motive function in behavior, as illustrated in Figure One. These are regulated by different processes that either perform regulation of the individual body by voluntary actions and cognitive appraisals in relation to the physical world, or through engagement with the bodily activities and psychological processes of other persons. Human intersubjective regulations, initially by direct communication of intentions, attentions and feelings in *synrhythmisis*, leads to learned cultural communication and regulation of meanings by means of symbols. Right: A map of the regulatory "field of emotions" and the major neurochemical mediations of emotional states (see Table 2.1). Showing relations between motive principles, neuro-chemical systems of physiological and psychological self-regulation, and engagements between the subject and different objectives and partners in behaviour. *Source:* From "Action and Emotion in Development of the Human Self, Its Sociability and Cultural Intelligence: Why Infants Have Feelings like Ours" (pp. 61–91), by C. Trevarthen, in *Emotional Development*, J. Nadel & D. Muir (Eds.), 2005a, Oxford: Oxford University Press.

and their pathologies are the *amygdala*, the *hippocampus*, and the *anterior cingulate gyrus* (see later discussion).

Planned allostatic regulations drawing on experience are acquired, accessed, and modified by *emotions*. Panksepp (1998a) has classified emotions and *affective neural systems* according to their regulatory functions (Table 2.2). Unplanned stress is met by mobilization of active defensive behaviors (fight with the emotion of RAGE), or by action-reducing withdrawal (flight with the emotion of FEAR). Energetic exploration and exploitation of environmental resources is served by the inquisitive emotional behavior of SEEKING. Self-energizing and rewarding emotions of JOY/PLAY/SOCIAL AFFECTION in well-being are shared with affiliative emotions of SEXUALITY, NURTURANCE/MATERNAL CARE, and SEPARATION DISTRESS/SOCIAL BONDING.

Understanding the emotional life of children requires interpretation of the intricate forms of expressions of emotion by which even newborn infants are capable of communicating their states of purpose and their concerns for comfort and security to other human beings (Darwin, 1872/1998). Vocal expressions, which change during development in their range and power, give subtle expression to muscle actions and tensions within the body (Scherer, 1986; Zei Pollermann, 2002). Eye movements signal the direction of interest and its changes with exceptional clarity in humans, because we have a white sclera (Kobayashi & Kohshima, 2001), and movements of the lower face express feelings of joy and sadness, of wonder and anger, and of liking or loathing (Darwin, 1872/1998). There is still uncertainty about how to classify facial movements and what psychological functions to attribute to them, de-

TABLE 2.2 Emotion Systems

Affective Behavior	Distributed Neural Networks	Neuromodulators
Ergotropic		
Seeking Exploratory behavior	Ventral tegmental area (VTA) to dorsolateral hypothalamus to periaqueductal gray (PAG), with diffuse mesolimbic and mesocortical "extensions." Nucleus accumbens as basal ganglia processor for emotional "habit" systems.	DA (+), glutamate (+), many neuropeptides including opioids, neurotensin, CCK.
Play, joy, social affection	Parafascicular/centromedian thalamus, dorsomedial thalamus, posterior thalamus, projecting to more dorsal PAG (the septum is inhibitory for play; the role of other basal forebrain and hypothalamic systems is not clear).	Glutamate (+), opioids (+ in modest amounts, – in large amounts), ACh (muscarinic +), ACh (nicotinic –) DA, NE and 5HT all appear to be (–).
Rage Affective Attack	Medial amygdala to bed nucleus of stria terminalis (BNST) to anterior and ventromedial and perifornical hypothalamic to more dorsal PAG.	Substance P (+) (ACh, glutamate + may act as nonspecific modulators).
Fear	Central and lateral amygdala to anterior and medial hypothalamic to more dorsal PAG to nucleus reticularis pontine caudalis.	Glutamate (+), ACTH, and neuropeptides (DBI, CRF, CCK, alpha MSH, NPY).
Trophotropic		
Sexuality	BNST and corticomedial amygdala to preoptic and ventromedial hypothalamus to lateral and more ventral PAG.	Steroids (+), vasopressin and oxytocin. LH-RH, CCK.
Nurturance, maternal care	Anterior cingulate to BNST to preoptic hypothalamic to VTA to more ventral PAG.	Oxytocin (+), prolactin (+), DA, opioids (both + in modest amounts).
Separation distress, social bonding	Anterior cingulate/anterior thalamus to BNST/ventral septum to midline and dorsomedial thalamus to dorsal preoptic hypothalamic to more dorsal PAG (close to circuits for physical pain).	Opioids (±) oxytocin (±), prolactin (±) CRF (+) for separation distress, ACh (–).

Notes: + = Excitatory; – = Inhibitory.

spite the fact that they are so rich in variety with such immediate emotive effects on other persons (Oster, 2005).

STRESS: NATURE, PSYCHOLOGICAL FUNCTIONS, AND STRESS DISORDERS

The term "stress" is used to describe a host of events affecting an organism's relationship with the external or internal environment. Because stress in ordinary language is often thought of as an effect or force, as in physics or engineering, rather than a cause or an adaptive process, as implied in the original use in medical science by Hans Selye (1956), there may be confusion about the definition and meaning of the word (Dunn, Swiergeil, & Palamarchouk, 2004; Pacak & Palkovits, 2001). Nevertheless, the concept of a stress process has proved indispensable for guidance of clinical practices that seek to protect or repair individual well-being.

Stress as an Adaptive Response

All organisms, from bacteria to mammals, have evolved self-protective mechanisms of response to taxing or threatening life events. Such events are often unpredictable in

their occurrence and may have effects that are uncontrollable, traumatic, or life-threatening. Stress triggers a wide range of adaptation processes, implicating a complex of physiological, cognitive, and emotional responses (Huether, 1996), eventually leading to the general adaptation syndrome, through the phases of *alarm*, *resistance*, and *exhaustion* (Rozman & Doull, 2003).

When we experience a situation as stressful, physiologic and behavioral responses are initiated, leading to *allostasis and adaptation* (McEwen, 1999). Anticipated and well-controlled stress can exercise and reinforce adaptive life activities, leading to improvements in efficiency and effectiveness of vital functions and behavior. Development is stimulated and strengthened by adaptive response to stress. However, damaging stress or trauma and pain reduces life effectiveness and requires recuperation and repair. Immediately effective defenses against fatigue, illness, and pain may incur long-term costs to the organism's physiological and psychological resources and thus lead to a need for rest and processes of recovery, or, in the most socially advanced species, for protective and therapeutic care from other individuals (de Waal, 1996; Preston & de Waal, 2002).

Responses to stress may result in important changes to the body; they may replenish energy by promoting fat

deposition, which can result in heart disease when the body does not burn off the energy it obtains from food. They stimulate immune cells to move to sites in the body where they are needed to fight an infection (McEwen, 2003). Stress responses can be powerful and their effects lasting. In animal studies, it has been found that even an hour-long stress can result in detectable structural changes in the brain, with a recovery period lasting for many months. Clearly, the stress response can have long-term impact on the behavior and the health of the organism and on the adaptive responses to subsequent stress events. This is relevant to the effects of child maltreatment on subsequent physical and emotional development, an area of investigation that has been termed developmental traumatology (DeBellis, 2001; DeBellis et al., 1999a, 1999b).

Basic stress reactions include automatic physiological adjustments; these are manifested in signs such as a greater release of *stress hormones* (*glucocorticoids*), a rise in pulse, respiration, and blood pressure, and contraction of the pupils. These reactions are in general beneficial changes that help to control or eliminate dangers to the body or the mind, to improve an organism's level of performance, and to regulate the inevitable cost of defensive responses to protect the vital resources of the organism. If not too intense, stressful situations may stimulate neuronal differentiation in slow-maturing parts of the brain with benefit to future learning processes, such as those that help a person discover ways to cope with stress or how to avoid its causes (Greenough & Black, 1992).

Corticosteroids, at high circulating levels, enhance acquisition, conditioning, and consolidation of an inescapable stressful experience. After fight-or-flight responses, corticosteroids reestablish homeostasis via feedback mechanisms (Korte, 2001). The organism needs to consolidate its memories of the predator's appearance, location, smell, and sound. This information may predict the occurrence and nature of the next encounter and thereby maximize the likelihood of survival.

Uncontrollable chronic, high-intensity stress, however, destabilizes established neural pathways and biochemical homeostasis, or compromises allostasis, the active autonomic control that adjusts psychological motives to anticipated adaptive demands (McEwen, 1999), with consequences that might endanger the integrity of a young individual directly and have indirect effects later in life, even to adulthood.

The term *hormesis* (meaning an "urging on" or "activation") is employed to designate the potential beneficial or "encouraging" effects of mild stress when it enhances the organism's future reactions to similar stress—by increas-

ing catabolic energy-mobilizing processes, enhancement of immune reactions, faster and more effective motor responses, reinforcement or reward from a subjective feeling of increased well-being, all of which help the organism to survive and adapt or learn. Hormesis in various forms is widespread among living organisms, from the *Drosophila* to humans. Studies of stress induced by radiation, heat, or chemical stimuli demonstrate that exposure to mild stress early in life frequently results in increased stress resistance later in life, increased longevity, and even retarded aging (Kristensen, Sorensen, & Loeschke, 2003). The effect of a mild stress is likely to be mediated by alterations in gene regulation and/or gene expression and by subsequent, permanent metabolic changes. Mild stress may also increase the rate of gene mutation, permitting the population of the organism to successfully adapt to a changed environment (Goho & Bell, 2000).

The social facilitation effect of mild stress on human behavior has been investigated by social psychologists since the nineteenth century, and the facilitative effect of cognitive, somatic, and emotional anxiety on the achievement of athletes has also been widely investigated and confirmed (Hardy, 1996; Jones, Hartmann, Blaschitz, & Desoye, 1993).

In summary, early stress can lead to a cascade of responses, either adaptive, in the form of hormesis, or maladaptive, and the latter can pave the way to different paths of development and different capacities for stress resistance in prenatal and early postnatal life. Traumatic experiences early in life impress confused paths of experience and expectation, with sidetracks that are felt to lead nowhere (Siegel, 1999).

The Hypothalamus-Pituitary-Adrenal System

The stress response involves activation of the two major regulatory systems: the sympathetic nervous system and adrenal medulla (SAM) and the hypothalamo-anterior pituitary-adrenal cortical system (HPA).

The SAM, the effort or fight-flight and system, is most strongly engaged in connection with such strong and active emotional states of fear and anger as are manifested in traumatic anxiety. Its activity results in an increase of the level of the glucocorticoids *adrenaline* (epinephrine) and *noradrenaline* (norepinephrine), with effects both in the periphery and in the brain.

The HPA is the distress or conservation-withdrawal system. Corticotropin-releasing hormone (CRH) released from the paraventricular nucleus of the hypothalamus stimulates the pituitary gland to produce adrenocorticotropin hormone (ACTH). These two hormones stimulate the adre-

nal gland to release cortisol, the principal glucocorticoid hormone. When the stressor is terminated, glucocorticoids inhibit subsequent ACTH release from the adrenal cortex.

There are several studies supporting the hypothesis that hypersecretion of CRH is a crucial factor in depression and anxiety disorders (Nemeroff et al., 1984). It has been shown that when CRH was injected into the brains of rats, it produced many of the signs and symptoms seen in patients with depression and/or anxiety disorders (Arborelius, Owens, Plotsky, & Nemeroff, 1999; Dunn & Berridge, 1990; Korte, 2001).

Limbic Mechanisms and Varieties of Stress Response

Activation of the amygdala, the anterior cingulate cortex, the hippocampus, the bed nucleus of the stria terminalis, and several brain stem regions responsible for regulating basic homeostatic functions of the individual and communication in social engagements can directly or indirectly affect the HPA circuit. The hippocampus and the anterior cingulate cortex are in a negative feedback relationship with the HPA axis, and the activation of the amygdala enhances fearful states and the stress response (Price, 2004). Research with animals, particularly rats and monkeys, has shown how these parts of the forebrain are essential for the emotional regulation of activity and experience and for active social relationships, and this knowledge has found important applications in child psychopathology (Allman, Hakeem, Erwin, Nimchinsky, & Hof, 2001; Amaral, 2003; Isaacson, 2004).

The Amygdala and the Cingulate Gyrus

Two components of the limbic system, the amygdala and the cingulate gyrus, are especially responsive to stress hormones. The *amygdala* is central in what are believed to be predominantly negative *emotionally arousing processes affecting learning* (Cahill, McGaugh, & Weinberger, 2001; Markowitsch, 1998; Price, 2004; Siebert, Markowitsch, & Bartel, 2003). In confrontation with information of a dangerous situation or a threatening social partner, the amygdala becomes active, and this is associated with manifestations of fear and anxiety, which lead the organism into a state of alertness, getting ready for flight or fight in the service of self-preservation (Adolphs, Tranel, Damasio, & Damasio, 1995; Aggleton, 1993; LeDoux, 2000). The high concentration of receptors for corticotropin-releasing factor in the amygdala, which are responsible for the release of corticosterone and ACTH, makes the amygdala especially sensitive to the influences of stress hormones (Gabrieli et al., 1995). Atro-

phy and vulnerability of neurons in this area may have severe consequences for the adaptive processing of life-threatening experience, emotional self-regulation, and the social consequences of a defensive attitude. In human adolescence, especially, attachment and the regulation of emotions of sympathy depend to a large degree on proper functioning of this part of the limbic system. Individuals with disorders of this system that cause them to display avoidance, fear, and aggression become more emotionally and also socially “blind,” unable to perceive, process, or respond in a normal fashion to social and emotional stimulation (Cicchetti, 1989; Joseph, 1999).

The *cingulate cortex* has many cortisol receptors. Together with parts of the prefrontal cortex, it mediates in executive or coordinated *goal-directed motor activity* (C. S. Carter et al., 1998; Stuss et al., 2002), which requires effortful behavior, highly efficient attention, and control of inhibitory acts (Fletcher, Frith, Frackowiak, & Dolan, 1996; Markowitsch, Vandekerckhove, Lanfermann, & Russ, 2003; Nieuwenhuis, Yeung, van den Wildenberg, & Ridderinkhof, 2003; Vandekerckhove, Markowitsch, Woermann, & Mertens, in press), as well as arousal of conscious action, excitation of visual imagery, reexperiencing, and emotional processing of experiences (Cabeza & Nyberg, 1997; Fletcher et al., 1996; Markowitsch, Thiel, et al., 2000; Markowitsch et al., 2003).

In a study of preschool-age children who have high levels of cortisol, Gunnar, Tout, de Haan, Pierce, and Stansbury (1997) found that glucocorticoids affect self-control and self-regulation, requiring strenuous effort. This is possibly due to the stress hormones acting on the cingulate cortex. Brain mapping studies confirm that there is a diminished response of the anterior cingulate cortex in the presence of emotionally relevant stimuli in PTSD (Bremner et al., 2004; Shin et al., 2001). Dysfunctional recruitment of this region in PTSD may, in part, mediate symptoms such as distress and arousal on exposure to reminders of trauma.

The Hippocampus

The *hippocampal formation* also has an important role in recording the circumstances of stress (Bremner et al., 2000; Bremner & Vermetten, 2004), as well as in the functions of spatial learning and memory that may be affected by stress (Piefke, Weiss, Zilles, Markowitsch, & Fink, 2003; Tulving & Markowitsch, 1998; Vandekerckhove, in press; Vargha-Khadem et al., 1997), that is, in mapping a story of places, events, and persons that have brought fear or pain. With the temporoparietal neocortex, the hippocampus functions in the acquisition of an awareness of the environment as a

place in which to live. Stress experienced before birth and extending through the postnatal period influences the slow increase in volume and the maturation of the hippocampus. The dentate gyrus of the hippocampus continues to develop after birth by neurogenesis (Malberg, 2004; McEwen, 2002; Van Praag et al., 2002).

Animal studies show that a chronic influence of glucocorticoids on the hippocampus leads to the loss of pyramidal neurons and decreased dendritic branching, and a massive acute production of glucocorticoids changes and reorganizes synaptic connectivity. Stress to the mother decreases the number of stress hormone receptors in rat pups, reducing the inhibition of the release of stress hormones, finally leading to hippocampal cell death. Prenatal exposure to stressful restraint or unavoidable electric shocks in rats led to elevated plasma ACTH and corticosterone levels and lower mineralocorticoid and glucocorticoid densities in the hippocampus (C. Henry, Kabbaj, Simon, Le Moal, & Maccari, 1994). Loss of function of mineralocorticoid (type I) receptors affects the capacity for selective attention and integration of sensory stimuli, whereas the impairment of glucocorticoid receptors (type II) affects consolidation and retrieval of information.

Prenatally stressed rats also showed more anxiety-like behavior in the elevated plus-maze test as adults than their nonstressed controls, and this behavior was positively correlated with stress-induced corticosterone responses (Korte, Buwalda, Meijer, de Kloet, & Bohus, 1995). If rats are separated from the mother after birth, they can develop extreme distress reactions (de Kloet, Korte, Rots, & Kruk, 1996). Longer periods (24 hours) of separation cause a rise in corticosterone. Rats deprived of their mother's attentions at the postnatal age of 3 days demonstrated hypercorticism (Rots et al., 1996). Stimulation from the mother protects against all these stress effects. High levels of maternal care (licking, grooming, arched-back nursing) decreased corticotropin receptor density and reduced fear of novelty in the offspring when they reached adulthood (Caldji et al., 1998).

Strong correlations have been found in humans between hippocampal volume and numbers of years of abuse or maltreatment (Bremner, 2002; Bremner & Vermetten, 2004). Severe stress causes a greater reduction in cell proliferation from adolescence to senescence, and early stress exposure accelerates a developmental reduction in hippocampal plasticity. In women, a significant correlation between total lifetime duration of depression and smaller hippocampal volumes has been found (Sheline, Sanghavi, Mintun, & Gado, 1999).

DEVELOPMENT: MUTUAL REGULATIONS IN MORPHOGENESIS OF A HUMAN MIND

In dealing with such a complex system as the developing embryo, it is futile to inquire whether a certain organ rudiment is "determined" and whether some feature of its surroundings, to the exclusion of others, "determines" it. A score of different factors may be involved and their effects most intricately interwoven. (Harrison, 1933)

Clinical evidence and information from research with animals confirms that stress responses can occur early in interuterine development. In some cases, fetal stress changes the course of postnatal development and has lasting effects. To interpret these better we need to relate them to the unique timetable and sequence of intrauterine human development, to the special environment in which developments occur, and, above all, to the maturation of adaptive structures and processes between the embryo and fetus and the mother's body. Communication between them, and regulation of states of activity and of stress, is two-way from the start and acquires psychological attributes months before birth.

The human organism and its constituent systems and processes—at all levels, from the single cell to a culture sustained by its customs and history of beliefs—have evolved with adaptations to live and change in communities of like systems and processes (Figure 2.3). The fertilized ovum arises from a cluster of maternal cells and divides after fertilization to form a differently organized group. This fuses with the tissues of the wall of the mother's uterus to create a closely integrated living assembly, a tissue with elements from the two bodies. Vital functions of a child's body and the developing brain and behavior require interaction with a mother's body in prenatal stages and with intimate parenting through infancy and early childhood. Essential features of this development are shared with other mammals, but human childhood is long and has additional needs for sharing activity and experience.

Fetus and mother, both in adaptive states of calm inwardness, interact by way of muscular activity—of the fetal body and of the mother's uterine contractions, heartbeat, breathing, and her whole-body movements—and by various senses. In the last trimester, they respond to one another and learn.

The human infant at birth is more helpless than a newborn monkey or chimpanzee and much more developed than a newborn rat or kitten. Above all, the human infant is born with unique powers of expression and intersubjective

communication of thinking (Hobson, 2002). A young baby tries to communicate self-generated purposes and interests, with emotional evaluations of experiences, including remembered or imagined ones. This condition is the adaptation of a species that employs psychological abilities of a highly evolved consciousness (Donald, 2001). This consciousness grows in a long period of dependence not only on maternal nurturance and paternal protection, but also on communication of interests and meanings in affectionate relationships with other family members and on learning with companions of all ages in play.

Both body and brain of a newborn baby have anatomical and functional adaptations for social support that lead to cultural learning. This requires, besides the linking in of systems that regulate the metabolism and energetics of behavior, affective coordination of motive processes for the acquisition of new intelligence and skills. These processes can be understood only if the *proactive, motor aspects* of engagement of the human organism with the environment and their *motivating initiatives and emotions in prospective processes of intending and imagining* are recognized, not just the sensory and perceptual processes that take in forms of information for experiences and categorizes them.

The cerebral circuits of innate human sociability adapted for this communion are founded on systems of the brain stem that were set out in the embryo (Trevvarthen & Aitken, 1994). The exceptionally long human fetal period augments these structures with great cerebral and cerebellar extensions that will make it possible for a child to assimilate the skills and knowledge of the parental culture. Far from being a blank slate, the newborn infant's brain is a waiting apprentice, primed to gain competence through intent participation in the purposes, experiences, and emotional concerns of other people (Rogoff, 2003), but ready to be resistant or challenging, too.

A child has to make efforts to find and make use of the experience of intimate care and affection. Problems with development arise when the child does not seek care in a normal way, as well as when the human environment is unresponsive or in some measure abusive, rejecting, or failing to perceive the child's motivation.

Body, Brain, and Mind: Prenatal Stages and Infancy

The life of any organism has come about through the slow process of evolution, a process of transformation of whole life histories (de Beer, 1945), and an evolution of social impulses and sensibilities that find their adaptations in whole communities. The inherent features are adaptive in

each case to the extent that their functions and development enable the living individual and the group to sustain well-being and gain advantage from acting in an "expected" environment.

We have set ourselves the task to examine how the developing human body and brain change through embryo, fetal, and infant stages, attempting to identify age-related periods of change and potential vulnerability and their effects in later life of that individual. This is, of course, not a new endeavor, but we believe that there is need for a fresh look to find more integrative concepts that might guide more effective diagnosis and treatment of neurodevelopmental disorders.

In human brain development, there is a long phase of prenatal growth of adaptive systems within the mother's body. This is succeeded by 2 years of infancy when the child is totally dependent on maternal care, or its equivalent provided by a mother substitute. Within the mother's body, there are few ways that the embryo or fetus can act to seek changes. Nevertheless, research on twins in utero with ultrasound shows that fetuses past midterm can act and react through contacts with one another, as well as with the mother's body (Piontelli, 2002). In the last trimester, the fetus learns the sound of the mother's voice and can move in response to the movements and tonus of her body, as well as react actively to chemical elements in the media shared with her (Lecanuët, Fifer, Krasnegor, & Smotherman, 1995).

After birth, there is a greatly expanded scope for action, for moving, and for sensing the effects. Infancy is a period in which most of the intelligent strategies for living and learning in a human world become effective, including the all-important maturation of activities of communication that engage the child's consciousness with the awareness, purposes, and emotions of other persons. After no more than 2 years, a normal child is well on the way to being a cooperative member of the community, starting to master language and a host of other cultural skills that depend on understanding and engaging with the minds of others (Trevvarthen, 2004b).

The Limits of Gene Theory for Explaining Psychopathology

Just as King John was deluded to imagine a baby could produce language with no human company, so a modern behavioral scientist is misguided if he believes a gene can determine either a normal psychological function or a

specific and consistent disorder. Metabolic, hormonal, neural, and other factors of the organism condition gene expression. In the end, a person's genetic constitution is just one factor in how he or she will appear, how he or she will act, know, and think, and how well his or her health will be.

The genetic constitution of a human being has its effects in critical developmental phases that are associated with specific processes that require input from the environment. *Experience-expectant* processes occur during periods when the brain is primed by its motivating or seeking activities and selective attentions to receive specific information from the environment (Cicchetti, 2002; Greenough & Black, 1992). In such periods, the brain is also producing an overabundance or "exuberance" of nerve tracts and synapses, which initiates a pruning or selective retention of elements by competitive interactions between neuronal connections for supportive or trophic factors (Edelman, 1987).

However, during sensitive learning periods, the brain is actively regulating the effects of input, and the most significant epigenetic constraint that determines what a human child's genes can accomplish after birth is that child's communicative and collaborative relationship with other persons. At the heart of this regulation of a human life course are the *emotions*, systems of neural and neurohumoral activity that keep the exploratory and executive functions of human agency on track and that regulate the moral quality of social commitments, thereby influencing every adaptive change in memory that the plasticity of the vastly retentive forebrain cortex permits.

Abnormal experience of parenting or social deprivation during experience-expectant phases of development may have enduring deleterious effects on neurobiological and behavioral epigenesis (Black, Jones, Nelson, & Greenough, 1998; Cicchetti, 2002). In the science of developmental psychopathology, a crucial principle is that the developing individual takes an active autopoietic role in the construction of a life course and in comprehending the meaning of life events (Cicchetti, 2002; Cicchetti & Tucker, 1994). The principle of *experience-dependent* synapse formation, and the neural plasticity or adaptive self-organization that mediates between nature and nurture throughout the life span, imply that each child's adaptation will be unique to that individual (Cicchetti & Tucker, 1994).

To appreciate the adaptive power of the epigenetic process described by Gregory Bateson (1979), we must survey how the structures that guide the assimilation of experience grow and become integrated in more and more elaborate self-regulatory systems of an organism, and how the

regulations of different individuals who are adapted to act together may collaborate at different stages to benefit this elaboration.

Prenatal Stages and Adaptations for Interdependency with the Mother

In the early development of a child, the cell mass generated by division of the fertilized egg is dependent for its life on intimate fusion with tissues of the mother. The immobile embryo stage, with its integrated body form, differentiated physiological organs and humoral and central nervous systems, begins to regulate its own vitality while attached to the mother's circulatory system by the placenta. Birth will be a sudden transition to a far more independent life, and in the final weeks of gestation there are preparations for this event, and for the new communications with other persons that will be needed. At every stage there is both a dependency on the living environment, and a new life process advancing its autonomy with the support of that same environment.

From the Beginning, There Is Collaboration between Organisms at Many Levels

Individuation, the making of a human being, begins with sex. Two unique gene arrays are brought together through engagement of two adults with their complementary reproductive systems. The process of mating and copulation between a man and a woman requires a delicate social interplay on many levels of communication. The same is true for the couple's sexual cells. Gamete cells work together with the physiology of the sexual organs to meet and combine.

Sperm motility is probably a minor factor in the fertilization process. Sperm are found in the oviduct within 30 minutes of deposition, a time "too short to have been attained by even the most Olympian sperm relying on their own flagellar power" (Storey, 1995). Rather, the sperm appear to be carried to the oviduct by the woman's uterine muscular activity. The activity of the female genital system working together with the male ejaculate sets the stage for fertilization.

A similar reciprocity of action is found near the ampullary region of the oviduct, where fertilization takes place. Fewer than 1 in 10,000 sperm get close to the egg region (Ralt et al., 1991). Those that do must pass through a process of capacitation, where the sperm cell membrane is altered by loss of cholesterol (Cross, 1998) and carbohydrates (Wilson & Oliphant, 1987), and its membrane potential becomes more negative through loss of potassium

ions. These and other negotiations of the sperm with the female genital tract are required before fertilization can take place (Töpfer-Peterson et al., 2002).

The egg is a remarkable storehouse of life-sustaining cytoplasmic molecules accumulated through oogenic maturation. The molecular supplies of energy and amino acids it holds support the early development of the embryo until it implants and fixes itself into the uterine lining. Ribosomes, RNAs, and morphogenetic factors are in place inside the egg to organize the many complex reactions of protein and nucleotide synthesis for the early cell divisions.

The sperm, in contrast, arrives with little more than its half of the genetic material and the necessary enzymes to digest the outer coverings of the egg for fusion and delivery of the genetic material. Its primary features are the motor organelle, or *flagellum*, the cell nucleus containing the haploid chromosomes, and an acrosomal cap that houses the digestive enzymes needed to lyse the egg's membrane for fusion. On reaching the egg, a sperm lines up parallel to its surface, the *zona pellucida*, and is actively tethered there (Baltz, Katz, & Cone, 1988). Egg sperm-binding proteins crosslink with receptors on the sperm surface, which appear to be responsible for the release of the acrosomal enzymes that dissolve the *zona pellucida*, causing the sperm cell membrane to fuse with the membrane of the egg (Leyton, Leguen, Bunch, & Saling, 1992). The process of sperm and egg fusion and subsequent gene delivery is an interactive process contributed to by both parties.

The Autopoiesis of an Individual Animal Agent

The fertilized cell, or zygote, with its new genetic potential and its new arrangement of cytoplasm, now produces a multicellular animal. Cleavage of the fertilized egg gives rise to 2, 4, 8, and 16 cells in the first few days after fertilization. Each cell has the capacity to become any cell type in the mature body; they are totipotent and can be extracted to form embryonic stem cells. From the 16-cell *morula* stage forward, however, they take courses of specialization that will eventually give rise to every diverse cell type in the human body.

At the 16-cell morula stage, cells on the inside develop into the *embryo*, but those on the outside become *trophectoderm* and give rise to the embryonic portion of the placenta, the *chorion*, which produces regulators of immune response so the mother does not reject the embryo. Chorion cells also cause the mother's uterus to retain the fetus and develop into a mingling of circulatory systems in the *placenta* that enables the fetus to get oxygen and nourishment from the mother (Figure 2.8). At the 32-cell stage, the *trophectoderm* has become distinct from the embryo proper.

Figure 2.8 Early fetus to show the attachment between the mother's tissues and those of the fetus by the placenta. The placenta constitutes an elaborate frontier for *amphoteronomic* regulation of the vital state of both fetus and mother. *Sources:* From *Human Embryology: Prenatal Development of Form and Function*, third edition, by W. J. Hamilton, J. D. Boyd, and H. W. Mossman, 1962, Cambridge: Heffer.

Interestingly, the cells of the embryo actively support this structure, secreting proteins that cause the trophoblast cells to divide (Tanaka, Kunath, Hadjantonakis, Nagy, & Rossant, 1998).

The cells of the embryo become organized into three lines with different potential functions: (1) The *ectoderm* will give rise to the outer layer of the embryo and its brain and central nervous system; (2) the *endoderm* becomes the innermost layer and produces the digestive tube and its associated organs; and (3) the *mesoderm* will form the muscles, bones, blood, connective tissue, and the rest of the somatic organs. It was recognized by the early anatomists that the germ layers do not develop on their own. As the embryologist Pander said, "... each layer is not yet self-sufficient enough to create what it is destined to be; it needs the help of its companions, and therefore, although destined for different roles, all three of them collaborate ..." (Pander, 1817, p. 12, original translation).

Reciprocity of relations between cells and between tissues drives embryological processes of body shaping. For example, the marking out of the anteroposterior embryonic axis depends on the inductive properties of two signaling centers: the *node* and the *anterior visceral endoderm* (AVE), which together determine the front end of the embryo (Bachiller et al., 2000); this will become the *head*, the lead center of the behaving individual with special receptive and signaling powers (Gans & Northcutt, 1983). The positions of the node and AVE themselves appear to be initiated by signals from the extraembryonic ectoderm, which

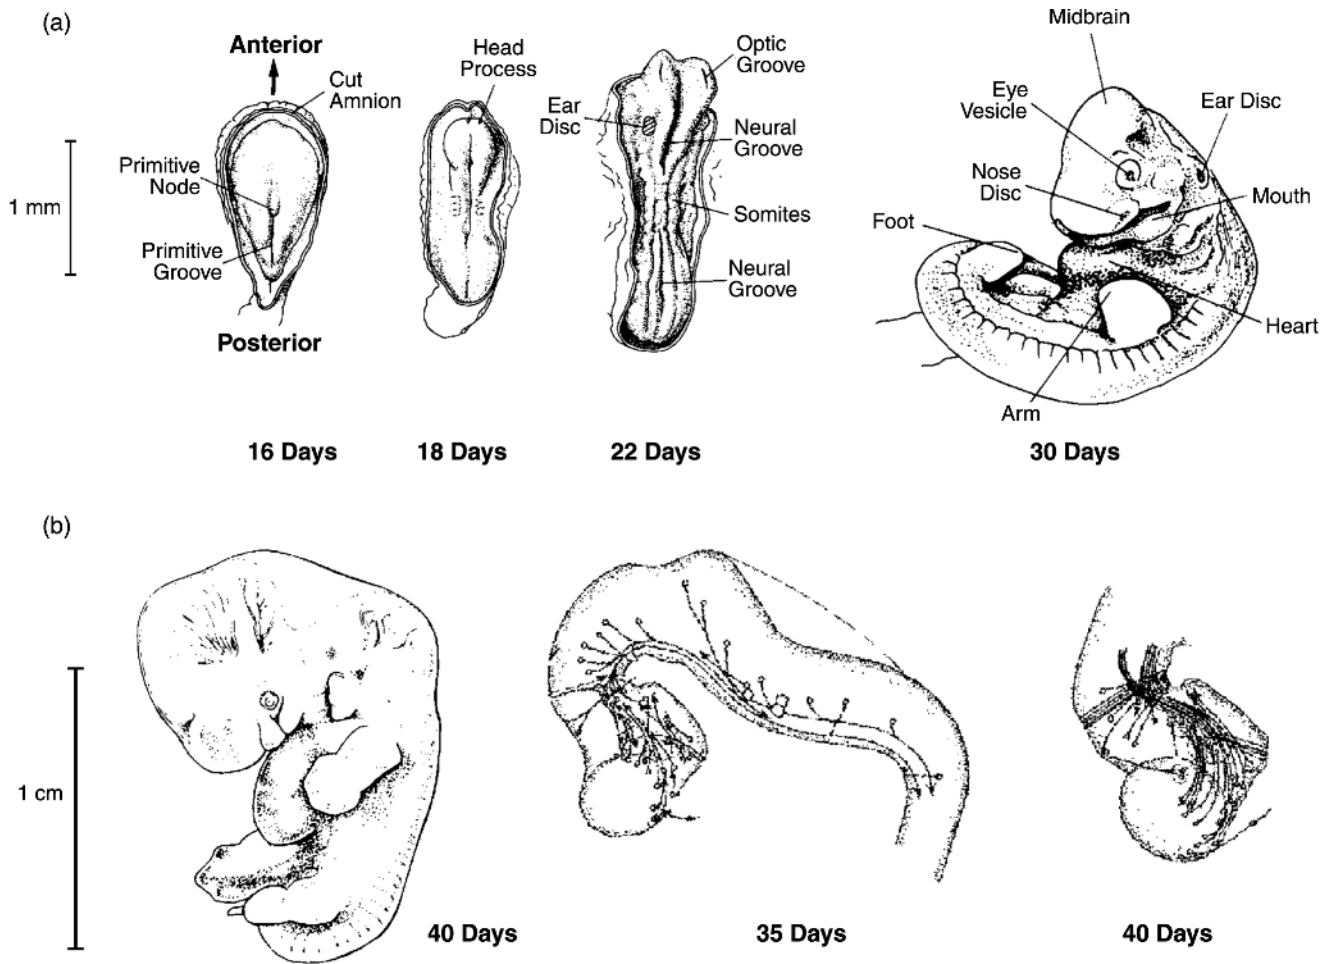

Figure 2.9 (a) Early embryos showing formation of the body and CNS. (b) Late embryo. On right, growth of the integrative tracts of the brainstem. *Source:* From “Brain Development” (pp. 116–127), by C. Trevvarthen, in *Oxford Companion to the Mind*, second edition, R. L. Gregory (Ed.), 2004a, Oxford, NY: Oxford University Press.

also induce the patterning of the visceral endoderm (Brennan et al., 2001), and by trophoblast Arkadia protein (Episkopou et al., 2001). Thus, cells from the extraembryonic trophoectoderm and embryonic mesoderm and ectoderm work together in shaping the initial body pattern of the early embryo in anticipation of an active life.

Embryos develop three axial gradients of molecular constitution as foundations of the body plan: the *anteroposterior* axis extending from head to tail, the *dorsoventral* axis from the back to the belly, and the *right-left* or *mediolateral* axis (Figure 2.9). An important group of genes in the developmental network are the *homeotic genes* that contribute to the control of specification and cell fate (W. Bateson, 1894; E. B. Lewis, 1994; Robert, 2001). Homeotic genes guide the formation of the integrative systems of the body and brain (Boncinelli et al., 1988; E. B. Lewis, 1998). Signaling elements map the body and its segments. Hedgehog genes produce morphogens in very early stages of the em-

bryo that appear to be crucial to the regulation of whole CNS polarity, with effects on nerve cell multiplication and axon growth at subsequent stages (Echelard et al., 1993).

One of the most well-researched signaling molecules is the small protein *Sonic hedgehog* (SHH). Patterning by SHH from the notochord specifies dorsoventral polarity in the neural tube; SHH signaling in the brain rhombencephalon, mesencephalon, and telencephalon is thought to perform similar functions leading to somatotopic mapping in brain nuclei and the molecular fields of cell surface and diffusible proteins that guide patterning of nerve tracts (Marti & Bovolenta, 2002). SHH in developing limb buds specifies anteroposterior arrangement of digits, and SHH shapes the external genitalia. Of particular importance, the SHH signaling centers work in feedback relationships with gene products from neighboring induced tissue and are themselves induced, forming dynamic developmental systems (e.g., see Scherz, Harfe, McMahon, & Tabin, 2004). They

induce and interact with other signaling centers, forming complex overlapping spatiotemporal developmental fields.

Morphogenesis of functional adaptive systems in the embryo is driven by cyclic processes of cell multiplication, migration, adhesion, selective cell survival or death, and epigenetic differentiation of cell functions into organs specialized for different regulatory roles, all dependent on reciprocal interactions between molecular cell surface events (determined by cell- or substrate-adhesion molecules) and activation or repression of gene activity (Edelman, 1988). Gene-regulating processes organize both the polarized and segmented body form and differentiation and integration of a coherent system of organs specialized for different vital roles. They define the ectodermal and endodermal surfaces of the body and the intermediary mesodermal sources of the skeletomuscular mechanisms of body action as well as the visceral, glandular, and circulatory systems and the fluid tissue of the blood.

A subdivision of the ectoderm, the *neurectoderm*, forms the CNS adapted to integrate volitional behavior of the whole body, its perceptuocognitive guidance, and its core regulatory emotional states that mediate between vital maintenance and adventurous engagement with the world. *Neural crest* cells, which proliferate at the margin of the neurectoderm, give rise to the autonomic nervous system. These neural control systems develop and connect with each other in interdependent concert with the somatic organs, musculature, and skeletal systems that develop from meso- and endodermal tissues. The hypothalamus and pituitary, which arise near the tip of the notochord in the location of the organizer region of the body (the *node*), are important centers responsible for production of hormones that will regulate processes of feeding, reproduction, and social affiliation in the developed individual.

We give here a brief account of how the tissues of the embryo are formed into a whole and coherent organism adapted not only for a future active life as an individual, but also for communication in the society of other human beings (Table 2.3). For more detail on the following summary of the formation of mechanisms for movement and perception in prenatal stages, see Trevarthen (1985), and for an outline of human brain development, see Trevarthen (2004a). Fetal activity, awareness, and learning are reviewed in Lecanuet et al. (1995).

Embryo: Vital Integration with the Mother's Body and Development of Human Form

An embryo human resembles the embryo of a lower vertebrate, such as a fish or a salamander. It has a central nervous system that mediates between the internal visceral

systems and the soma. The latter will become the active agent for a life of free mobility, with special sensory systems for perception of the outside world. After 2 months, when the body has a distinctively human form, the cerebral hemispheres are just starting to develop.

Early Embryo (0 to 30 days)

In the first 10 days, the fertilized egg develops a protective *amniotic cavity* and a nutritive *yolk sac* and joins with the mother's life support system by means of an elaborate *chorionic sac* with many selective functions (Figure 2.9; Table 2.3). The *body axis* of the embryo is determined, the notochord appears, and mesoderm cells migrate between the ectoderm epithelium facing the amnion chamber and the endoderm epithelium facing the yolk sac. The embryo may divide in two to create homozygous twins, which, in spite of their genetic likeness, rarely develop into twins that are identical in character (Piontelli, 2002). The time of division, between 3 days and 2 weeks, determines whether the two embryos will have separate placentas and amniotic and chorionic membranes (as in all dizygotic twins), or if some or all of these structures will be shared. Division after 14 days leads to fused, or Siamese, embryos.

By 20 days, the body is polarized with left-right symmetry, the neural plate is defined, and the head process forms. A simple *circulatory system* appears between the embryo, the yolk sac, the connecting stalk, and the chorion and brings a rich food supply from the mother's blood. As the chorion develops, the yolk sac shrinks. Distances in the embryo are now too large for nutrition by diffusion; blood must circulate between the embryo and chorion, which develops rapidly from the 9th to the 20th day, when the *placenta* is established. It will enlarge with growth of the fetus. The placenta is an important endocrine regulator for the fetus, functioning as a barrier to maternal catecholamines and other substances, filtering out stressors, including cortisol (Jones, 1993). Melatonin does pass over the placenta and seems to be the agent that informs the fetus about the mother's day-night cycle, thus preparing for them to have synchronized circadian rhythms (Yellon & Longo, 1988).

In the next 10 days, the *neural tube* closes, *body segments* form with *muscle somites*, and rudiments of *special sense organs* of the head and at the tips of the digits appear. The neurectoderm develops either brain or cord tissue dependent on induction from the ectoderm/mesoderm ratio in the cell masses. The *hypothalamus* develops in the organizer region at the end of the notochord, the first motor nerve axons grow from the spinal cord, and dorsal sensory ganglia form. At this stage, *somatic and visceral columns* are defined in the CNS. The *locus coeruleus* differentiates.

TABLE 2.3 Developments in Embryo and Fetus

	Early Embryo	Late Embryo	Early Fetus	Midfetus	Last Trimester
Days from conception	0–30	30–60	60–100	100–200	200–280
Body length, mm	0.03–5	5–30	30–100	100–270	270–340
Body form and CNS development	Embryo linked to mother's body by placenta. Germ layers and body form defined. Neural tube forms and body segments appear. Hypothalamus, somatic and visceral columns in CNS, and locus coeruleus differentiate. Serotonin is present.	Main brain centers, special sense organs, and brain stem tracts and nuclei. First noradrenergic, then dopaminergic systems appear. Serotonergic neurons appear in the forebrain. Amygdala and hippocampus differentiate, with the basal ganglia.	Neocortex develops afferent and efferent tracts. Serotonin assists cortical cell differentiation and network formation. Neuroblasts develop first in hippocampus and pyriform cortex. Sexual differentiation is initiated and HPA system matures.	Right hemisphere more advanced than left. Autonomic system sufficient to allow viability in incubator from 170 d. Cholinergic activation of cortex from 140 d. Axons and dendrites of neocortex cells start growth from 180 d. Brain waves start 170 d. Habituation to vibratory stimuli develops from 160 to 210 d.	Neocortical cell dendritic fields grow. Axons extend to brain stem and commissures grow between hemispheres. Visual cortex cells functional from 250 d. EEG develops rapidly, but is unreactive to stimuli. Sleep-wake cycle starts 260 d. Dopamine turnover high, GABA and glycine switch from excitatory to inhibitory function. Glutamate and aspartate increase with noradrenaline and neuromodulator galanin.
Movements		Axial twisting movements start at 50 d.	Head and arm movements, respiratory, jaw, and swallowing movements appear after 80 d.	Arm and hand movements increase and are guided by touch to explore body of fetus and surrounding objects. Postural and gestural movements show asymmetries. Heart rate changes coupled to movements from 170 d.	Respiratory movements increase. Body movements decrease. Face, tongue movements smiling, eye movements and hand gestures increase. Fetus sleeps, but wakes easily from 230 d. At term, spontaneous, automatic movements respond to perceptual guidance. Eyes open and active from 230 d.
Sensory systems and perception		Touch responses appear at 50 d.	Responses to the mother's body movements, or movements of a twin, are possible.	Vestibular responses by 100 d., auditory from 150 d., and visual from 180 d.	All sensory-perceptual systems are active before term, excepting the cortical visual system, which undergoes rapid development postterm. Fetus interacts with maternal movements and uterine contractions and learn mother's voice.

Mossman, 1962, Cambridge, England: Heffer; "Development of Neurotransmitter Systems during Critical Periods," by E. Herlenius and H. Lagercrantz, 2004, *Experimental Neurology*, 190(Suppl. 1), pp. S8–S21; "Neuroembryology and the Development of Perceptual Mechanisms" (pp. 301–383), by C. Trevarthen, in *Human Growth*, second edition, F. Falkner and J. M. Tanner (Eds.), 1985, New York: Plenum Press; and "How Infants Learn How to Mean" (pp. 37–69), by C. Trevarthen, 2004b, in *A Learning Zone of One's Own* (SONY Future of Learning Series), M. Tokoro and L. Steels (Eds.), Amsterdam: IOS Press.

At 30 days, the cerebral hemispheres are small, thin-walled sacs with undifferentiated neuroblasts.

Late Embryo (30 to 60 days)

In the second half of the embryo period, the main components of the brain have been formed, and *eyes*, *vestibular canals*, and *cochlear*, *nose* and *mouth*, and the *hands* are rap-

idly differentiating their distinctive forms, each dedicated to the picking up of a particular kind of physical information from the environment in selective ways (Figure 2.9; Table 2.3). For most of this period, the nervous system has no electrical activity and generates no movements, and the cerebral hemispheres and cerebellum are rudimentary. In comparison, the *brain stem cell groups and tracts* are well

formed (O’Rahilly & Müller, 1994). They will function as the intrinsic motive formation (Trevvarthen & Aitken, 1994), activating the behavior of the whole organism.

The pathways that will supply input from the environment and excite movements now develop. First, descending efferent, then ascending pathways grow from the brain stem to the spinal cord, and the first monoamine pathways grow from the brain stem into the primordial cerebral hemisphere. Retinal fibers grow to the midbrain optic tectum, and other sensorimotor circuits of brain stem and spinal cord are formed. *Noradrenergic* neurons, later to be involved in arousal and attention, fear and anxiety, and learning and memory, appear in the CNS around 35 to 40 days. *Dopaminergic* neurons appear a little later, at a gestational age of 40 to 55 days. They will become important after birth in motor and cognitive or executive programs (Herlenius & Lagercrantz, 2004).

Throughout the development of the central nervous system, synaptic activity, with interneuronal transmitter activity, is required for the survival of the synapses. Inactive neurons suffer selective loss, or apoptosis. Very early synapses are special, however, because they require neither generation of action potentials nor the calcium ion transportation and vesicle fusions for their maintenance.

Neurotransmitters appear as the integrative systems of the CNS are forming. Enzymes to synthesize the *catecholamines*, noradrenaline (norepinephrine) and dopamine, appear in the first 2 days in the chicken embryo. In primates, catecholaminergic neurons appear in the midembryo period, at the time when the telencephalic vesicle is forming.

Neurons producing *noradrenaline* appear at 35 to 40 days in the human embryo (Sundstrom et al., 1993). They influence the generation, migration, and maturation of the cortical neurons. The birth of the first cortical neurons, the Cajal-Retzius cells, is regulated by the noradrenergic system (Naqui, Harris, Thomaïdou, & Parnavelas, 1999).

Dopamine appears at around 40 to 60 gestational days in humans and is produced in the fetus at a very high level compared to adults (Sundstrom et al., 1993). Dopamine acting on the D1 receptors, which are abundant prenatally (Boyson & Adams, 1997), can directly affect gene transcription. Experimental research shows that even subtle changes in the neurotransmitter systems can directly influence early brain development. Dopamine antagonists during the prenatal period can prevent apoptosis, and lesioning noradrenergic projections prevents glia cell proliferation and in the perinatal period leads to abnormal cortical differentiation (Berger-Sweeney & Hohmann, 1997; Herlenius & Lagercrantz, 2004).

Serotonin (5-HT) can be detected in the fertilized egg and already affects the development of various organs and structures. Serotonin in the early prenatal period is also transported through the placenta from the mother. Serotonergic neurons of the forebrain appear at about 35 to 80 days in humans. The population of serotonergic receptors peaks in midgestation, precisely at the time of a very active neurogenesis, including maturation of the hippocampus. By birth, these receptors are present throughout the cortex, then are reduced rapidly at around 3 weeks after birth. Decreased serotonin levels during the early fetal period may lead to later neurodevelopmental disorders, such as Autism (D. C. Chugani, 2002). The postnatal peak followed by a subsequent decline in the level of serotonin typical of children without Autism is not seen in the brains of children with Autism.

The *amygdala* and *hippocampus* begin rapid differentiation around 50 days, with fiber connections through the lateral forebrain bundle, and the septum develops cholinergic nuclei. The *corpus striatum*, a central coordinating mechanism for adaptive movement routines, is a conspicuous swelling at 40 days. The *neostriatum*, *caudate*, *substantia nigra*, and *globus pallidus* establish mechanisms of basic instinctive motor functions.

The *oculomotor nucleus* differentiates and the *cerebellum* and *cochlear nucleus* receive cells from the proliferative zone in the hindbrain roof (rhombic lip) as the hindbrain *visceral sensory nuclei* develop. Brain development is linked with differentiation of the *gonads* and *sex organs*. The special sense organs (*eyes*, *nose*, and *mouth*, *vestibular canals*, and *cochlear*, *fingers*, and *toes*) are now miniatures of their final form (Figure 2.10). The fetus is hunched, hands up in front of mouth and eyes, the right hand higher than the left in most.

The wall of the *cerebral hemisphere* (*neocortex*) begins differentiation at about 60 days. Cortical neuron cell types (stellate cell, pyramidal cell, etc.) are determined before cells reach their place in the cortex, grow dendrites, and receive afferents. Brain stem afferents to the cortex are guided by position-specific molecules and influence cortical cell development. Efferent fibers do not grow from cortical cells until about 60 days.

Fetus: Preparing the Body and Brain for Intelligent Activities and a Sociable Life

The mammalian brain, with its large neocortex, gains its distinctive form in the fetus. Activated and directed by the core motivating processes of the brain stem, the cortex will assimilate a complex consciousness by engaging with

Figure 2.10 Early fetus, 60 days, with well differentiated special sense organs—eyes, nasal passages and mouth, hands, feet, semicircular canals of the vestibular system, and cochlear—at a stage when movements are just beginning and sensory terminals in the CNS have not formed. *Source:* From “Brain Development” (pp. 116–127), by C. Trevarthen, in *Oxford Companion to the Mind*, second edition, R. L. Gregory (Ed.), 2004a, Oxford, NY: Oxford University Press.

physical and social worlds. In the final weeks of fetal life the expressive organs and receptors that will couple the emotions of the child to those of parents as teachers are readied for action, and the unborn infant starts to learn an attachment to the mother’s person.

Early Fetus (60 to 100 days)

Throughout its development, the *neocortex* is intimately and reciprocally connected with the earlier formed nerve systems of the brain stem and cerebellum that will control actions of the body and generate autonomic self-regulations and the emotions of social signaling (Holstege et al., 1996; Panksepp, 1998a; Figure 2.10; Table 2.3). Neurogenesis of the cerebral cortex begins.

Serotonergic (5HT) cells appear at about 35 to 84 days in the human (Herlenius & Lagercrantz, 2004). These cells send axons to the forebrain and may be of importance in

the differentiation of neuronal progenitors (Gaspar, Cases, & Maroteaux, 2003). Miswiring problems due to excess or inadequate activation of specific 5HT receptors during development may be involved in the genesis of psychiatric problems, such as anxiety disorders, drug addiction, and Autism (for review, see Gaspar et al., 2003).

Neocortical neuroblasts begin to accumulate in the primordial *hippocampus* and *pyriform cortex (paleopallium)*. The latter receives olfactory axons and is a vestige of the main object-identifying and social response system of primitive vertebrates (MacLean, 1990). The neocortex is committed to receive ordered input of sensory information from the body surface and special distance receptors.

The special sense organs that formed in the late embryo become effective in exciting responses in a fixed sequence: touch to some parts at 50 days, vestibular sense at 100 days, auditory response at 150 days, and vision at 180 days (Ronca & Alberts, 1995). But the receptor surfaces are protected from stimulation before this, while the forebrain cortex cells are rapidly proliferating and thalamocortical projections are forming. The eyelids fuse at 50 days and reopen at about 170 days. Transmission of sound by the ear is blocked during the same period, the mouth is closed, and there are skin pads over the tips of the fingers.

Efferent fibers now grow from neocortical cells to thalamus, midbrain, and cerebellum. Subthalamic visual and auditory centers (superior and inferior colliculi) develop their circuits. Long corticocortical axons grow within and between the hemispheres, molding cortical folds that multiply throughout the fetal stage.

Control of *sexual differentiation* by *steroid hormones* is related to regulation of gene expression in the CNS. At 60 to 80 days, the *hypothalamus* with the medioventral reticular formation and the endocrine system of gonads and adrenals regulates development of the body and its secondary sexual features.

Now the fetus begins to move. Simple *axial twisting movements* of the body can be detected from around 60 days. Movements increase as axodendritic and axosomatic synapses form in the cortex from this time, and the number of *arm movements* increases from about 70 days. Movements influence development of tactile and vestibular systems and the face; respiratory movements affect lungs; swallowing affects formation of the mouth; and joint development benefits from limb movements (Ronca & Alberts, 1995). Fetal movements also begin to communicate with the mother through stimulating her body.

Many *hand* and *head movements* are made by 90 days, when there is a second phase of synaptogenesis, and gen-

eral, cyclic movements remain throughout gestation, resembling movements of the neonate.

Nerve cells form in the cortex from 60 to 120 days, and *cortical cell death (apoptosis)* starts. Cell numbers are essentially stable from 140 days, but there is cell loss later in development. Rapid growth in the fetal cerebral wall and folding of the cortical mantle is due to neuron enlargement and *dendrite* growth.

Midfetus (100 to 200 days)

Postural and gestural movements of the fetus show *asymmetries*, and a preference observed in self-stimulatory thumb-sucking in individual fetuses of 15 weeks gestational age correlates with hand preferences seen in the 2nd year after birth (Hepper, 1995; Table 2.3). The *right hemisphere* is more advanced than the left from about 170 days to the 2nd postnatal year, apparently due to asymmetric input from subcortical systems. It is more involved in trophotropic regulations than the left hemisphere, which is richer in dopaminergic systems (Trevvarthen, 1996; Tucker, 2001) and will take the lead in regulation of early communicative responses to maternal care (Schore, 1994).

At 140 days, fetuses are active approximately 25% of the time, moving about once per minute, and can actively regulate their nutrition and protein metabolism by *swallowing* amniotic fluid. From this stage until term, fetal heart rate slows appreciably and becomes more variable due to increasing parasympathetic maturation. At 170 days, the neurological and metabolic machinery for *self-maintenance* without placental support is sufficiently advanced for an infant to be viable in an incubator. The change is a sudden one, the 6-month-old fetus having achieved a characteristic state of relative functional readiness or autonomous regulation (Als, 1995).

The motor activity of the fetus is due to the maturation of neuroneuronal and neuromuscular transmission systems. The *cholinergic* activation in the human brain starts at around the 20th week of gestation (Herlenius & Lagercrantz, 2004).

Last Trimester (200 to 280 days): Preparation for Birth

Axons and *dendrites* grow from cortical cells between 180 and 260 days, following the order of the formation and migration of the cells into the cortex: first those that project to subhemispheric sites, then those that project within the hemispheres or across the *commissures* between them (Table 2.3). Visual cortex cells show changes anticipating thalamic input from the retina from about 250 days. Around 200 days, *inspiratory movements* of the chest and

responsiveness to vibroacoustic stimuli increase, related to cortical regulation of autonomic processes. Body movements decrease, and simple movements of the mouth and the tongue increase and rhythmic *mouthing movements* are present from 240 days in healthy fetuses. *Facial expressions, tongue movements, scowling, eye and mouth opening, blinking, yawning, smiling* are present in third trimester fetuses, as in neonates. Fetuses learn and are able to *habituate* to vibratory stimuli and “remember” them even 24 hours later.

At 230 days, the fetus is more alert and better coordinated, *waking* easily to stimulation, and showing the first *spontaneous eye movements* with lids wide open. The infant may raise *hands* to face, place them in the mouth, and suck them actively and rhythmically. Exploratory grasping occurs. For most of the last trimester the fetus is in a sleepy state, however.

The brain stem reticular formation, which will regulate sleep, spontaneous orienting, and consciousness after birth, exhibits patterned *electrical activity* first in the *pons*, at 70 days. The activity then advances through the *midbrain reticular formation* and basal ganglia, spontaneous *rhythmic brain waves* appearing in scalp electrodes at 170 days. At the time the fetus becomes viable, the *electroencephalogram* (EEG) becomes more regular, with bursts of theta waves (4 to 6 cps) synchronized within each hemisphere. Within a week or 2, this isosynchronism diminishes. At 210 days, higher-frequency bursts become more common (10 to 14 cps), this being the period of most rapid development of the EEG (170 to 250 days). There are still no electroencephalic reactions to stimuli and no sleep-wake differences. Activities at this time are probably of subcortical origin.

A distinction between *sleep* and *waking* tracings appears at 260 days. The waking EEG is similar to that of the full-term infant, but the sleep record differs, characteristics of the much younger (210 days) EEG reappearing in light sleep. Habituation to a vibratory stimulus has been studied to test responsiveness and regulation in fetuses. It is observed from about 160 days and finishes development at about 210 days, females being approximately 3 weeks earlier than males (Hepper, 1995).

The *dopamine* turnover is relatively high during the perinatal period, compared to adults. Extremely high levels of D1 receptors have been reported in the pallidum during the perinatal period (Boyson & Adams, 1997). D1 receptor stimulation regulates transcription of other genes, and it is possible that abnormal perinatal stimulation can result in long-term consequences (Herlenius & Lagercrantz, 2004).

Twenty-five to 40% of neurons contain *gamma-aminobutyric acid* (GABA), which switches from a prenatal excitatory function to an inhibitory function after birth with the appearance of the K+/Cl-KCC2 cotransporter at around 1 week of age (Miles, 1999). *Glycine*, another inhibitory amino acid neurotransmitter, similarly switches from excitatory to inhibitory function in the spinal cord and the brain stem. The disappearance of the automatic regulatory neonatal reflexes is related in part to the switch to inhibitory functions of these neurotransmitters (Fitzgerald, 1991).

Almost half of the synapses in the brain contain *glutamate* or *aspartate*, the main excitatory neurotransmitters that are most abundant around 1 to 2 years after birth in the human brain (Benitez-Diaz, Miranda-Contreras, Mendoza-Briceno, Pena-Contreras, & Palacios-Pru, 2003). Various other amino acids also show peaks and pre- or perinatal surges. They are abundant in the brain with slow transportation and slow effect and are often cosynthesized and stored with various other neurotransmitters. Many have a neuromodulatory function; that is, they assist in regulation of the synthesis and expression of the principal neurotransmitter molecules. For example, approximately 80% of the noradrenergic neurons contain *galanin*, a neuromodulator, which may control the rapid increase of noradrenergic release at birth (Herlenius & Lagercrantz, 2004).

Production of several neurotransmitters is activated around birth. The surge in the production of *noradrenaline* may contribute to the development of affectionate bonding between the mother and infant by increasing somatosensory attention (awareness of touch and temperature stimulation) and the interpersonal communication of motives of the newborn child (Sullivan, Wilson, Lemon, & Gerhardt, 1994). On the other hand, neonatal stress, including pre- and perinatal hypoxia, affects the expression and level of neurotransmitters and their receptors, and such changes could be a factor in the future mental health of the child.

Research on the behavior, psychology, and physiology of the fetus indicates that in the last trimester, functions are established in anticipation of an active postnatal life, and especially for assimilating and collaborating with maternal care (Lecanuet et al., 1995). Motor coordinations exist that are obviously adapted for visual exploration, reaching and grasping, walking, and expressive communication by facial expression and gesture (de Vries, Visser, & Prechtl, 1984, 1988; Prechtl, 1984). *Respiratory movements* and amniotic breathing appear several weeks before birth, and *heart rate* changes have been coordinated with phases of motor activity from 24 weeks (James, Pillai, &

Smoleniec, 1995). This is indicative of the formation of a prospective control of autonomic state coupled to readiness for muscular activity on the environment, a feature of brain function, which Jeannerod (1994) has cited as evidence for the formation of cerebral “motor images” underlying conscious awareness and purposeful movement. Both heart function and respiratory movements are stimulated by maternal hormones and contractures of the uterus that are both spontaneous and stimulated by oxytocin (Nathanielsz, 1995). Contractures can alter the oxygen level of the fetus by affecting placental circulation and secretion of cortisol and other hormones that might be both cause and effect of brain developments. Unlike a mature brain, which reacts to deoxygenation by a panic response, a fetal brain reacts to a drop in oxygen by protective withdrawal into inactivity.

Birth and Infancy: Regulations with a Growing Body and Brain and Development of Shared Experience

A normal birth is a highly collaborative process, the mother's body being influenced by her own hormonal system and by stimuli from the infant. In turn, the infant receives stimulation and mechanical effects from delivery that assist the onset of breathing, the transition from umbilical to pulmonary respiration. “Fetal brain expectation,” readying for postnatal life, is evident in developments of prematurely born infants (Als, 1995).

Newborns with a well-integrated regulation of activity and awareness as measured by EEG sleep patterns have more successful interactions with the mother and fewer problems in later childhood and adolescence (Parmelee et al., 1994). Quiet sleep, which is a state of restful disengagement from the environment, is related to cognitive functions from early infancy through childhood, but not so consistently to attention measures. Active sleep of the neonate, which is more easily disrupted or distracted by stimuli, correlates with vigilant attention in childhood, and it correlates with regulation of norepinephrine in the frontal cortex and wakefulness. What are called indeterminate sleep patterns of the newborn indicate poor state organization and are prognostic of poorer performance on both cognitive and attention measures in childhood. Left hemisphere EEG power spectrum analysis confirms other indications that the left hemisphere is adapted for vigilance rather than recuperation, which correlates with evidence that the role of the right hemisphere, and especially the right orbitofrontal system, is complementary for establishing close regulatory affective links with the mother in in-

fancy (Schor, 1994) and perhaps for more sustained rather than shifting vigilance (Posner & Petersen, 1990). “Poor social interactions and general socioeconomic circumstances amplify the negative effects of poor state organization, and good social interactions and socioeconomic circumstances diminish the effect confirming state organization as important for the biological environmental interface” (Parmelee et al., 1994, p. 550).

Adaptations for Mothering, on Both Sides

Newborn infants, like young of other mammalian species, are prepared for state regulation within maternal care (C. S. Carter, Lederhendler, & Kirkpatrick, 1997). They respond to the touch, movement, odor, and warmth of a mother, and sleeping with the mother may help the development of cardiac and respiratory self-regulations (McKenna & Mosko, 1994). With regard to the regulatory importance of skin contact, it is of great interest that human hair follicles can synthesize cortisol, and this is regulated by hypothalamic and pituitary hormones, including ACTH, β -endorphin, and CRH. Thus, hair follicles assist in the coordination stress response and integrating with changing metabolic demands and neuroimmune signaling circuits (Ito, Ito, & Paus, 2005). There are positive effects of gentle massage and other forms of tactile stimulation for premature infants (Field, 2003), and these can be related to how normal mothering of the newborn involves much gentle touching of the baby (Kennell et al., 1974). Rat pups gain regulatory benefit from maternal stroking or licking, and very small preterm human neonates given tactile-kinesthetic stimulation gain more weight per day, spend more time awake and active, and show more mature habituation, orientation, motor, and range of state behaviors on the Brazelton assessment (Schanberg & Field, 1987).

Infant's arousal and expressions of distress are immediately responsive to stimulation from breast-feeding, including responses to the sugar and fat content of breast milk (Blass, 1996), and this physiological response is already linked with a sympathetic psychological or interpersonal awareness; it is facilitated if the newborn has sight of the mother's eyes (Zeifman, Delaney, & Blass, 1996). Full-term newborns show not only orienting to the nipple by so-called rooting reflexes, but an impressive control over the complex movements of suckling and swallowing for breast-feeding (Craig & Lee, 1999), and the mother has, of course, many adaptations of body, behavior, and hormonal control of milk production, stimulated by the hormones oxytocin and prolactin, that help her feed the baby.

Getting Ready to Communicate Thought and Learn Signs of Thought

The remarkable, and only recently adequately explored, abilities of newborn infants to imitate communicative expressions of adults in many forms is but part of a highly coordinated adaptation to regulate or negotiate intersubjective contact (Hobson, 2002; Trevarthen, 2005a; Figure 2.11). The attempts of the infant to imitate are accompanied by efforts to “invite” or “provoke” return imitations from the partner. Moreover, these behaviors are associated with heart rate changes that indicate *imitating* is carried out in an energetic excited phase, marked by *HR acceleration*, whereas *provocations* are accompanied by an oriented and attentive or watchful state and *HR slowing* (Nagy & Molnar, 2004).

The regulatory mechanisms of the infant brain are reactive to endocrine steroids and other hormones (McEwen, 1989, 1997a, 1997b; Suomi, 1997), but they are also ready at birth to formulate and express motivated behaviors, including coherent emotions. An intricate *mutual psychobiological dependency* is set up between a newborn infant and the care of a mother or mother substitute (DiPietro, Irizarry, Costigan, & Gurewitsch, 2004). Modern perinatal medicine finds evidence that this system of regulation cannot be fully replaced by artificial clinical mechanisms (Als, 1995), and there are concerns that the increase of elective or medically advised cesarean births may violate the principles or mutual hormonal regulation between fetus and mother in the process of natural birth (Nissen et al., 1996).

Newborns, and possibly fetuses, too, react to and gain regulation from the rhythms of maternal breathing and heart beat (McKenna & Mosko, 1994), and fetuses and infants are also supremely sensitive to maternal vocal patterns (DeCasper & Fifer, 1980; Fifer & Moon, 1995; Hepper, 1995). These emotional responses to caregivers must play a crucial role in the regulation of early brain development (Als, 1995). They are likely to guide differentiation of perceptual discrimination, cognitive processing, memory, voluntary deployment of attention to environmental objects, and executive functioning or problem solving (Schor, 1994; Tucker, 1992).

Long before the oral-vocal system is skilled in imitating speech and using it, or the hands can use symbols in a sign language or writing, the eyes, hands, face, and voice of an infant may move in coordinated exchanges of expressions of feeling with an attentive and sympathetic partner. The mechanisms for vocal expression of emotion and those for speech that develop around midgestation (de Vries et al.,

(Eds.), 2005c, Cambridge, MA: MIT Press.

1988; Piontelli, 1992; Prechtl, 1984) are organized around nuclei of the brain stem and the basal ganglia, thalamus, and limbic cortex (Ploog, 1992; Trevarthen, 2001b). These are structures that Paul MacLean (2004) identifies with the reptilian instinctive motor complex (R-complex) important in the evolutionary background of communicative behavioral routines in mammals, and which are greatly elaborated in humans.

Multimodal brain stem circuits would seem to be crucial to communication with neonates and for their first imitations, which develop into well-controlled protoconversational abilities by 6 weeks, before visual awareness has undergone rapid development in the first 6 postnatal months. Developments in the mesolimbic cortices of the temporal and frontal lobes in infants and toddlers trans-

form autonomic self-regulation, emotions in communication, and the motives for action and experience (Schore, 1994, 1998). At all stages, limbic and neocortical circuits emerge in reciprocal, dynamic, and increasing involvement with the multimodal core regulatory systems of the intrinsic motive formation (Trevarthen & Aitken, 1994) formed in utero (O’Rahilly & Müller, 1994; Panksepp, 1998a; Robbins, 1992; Tucker, Derryberry, & Luu, 2000).

Brain Events in the 1st Year

There are major transformations in brain structure and function during the 1st year of infancy: in electrical activity and EEG coherence, cortical cell anatomy and connections, myelinization, brain metabolism, neurochemistry,

synaptogenesis and synaptic activity, receptor site multiplication and activation or deactivation, and gene activity (Dawson & Fischer, 1994; Nelson & Luciana, 2001). Charting of these changes with infants at accurately known ages after birth and with fine enough discrimination of different brain systems is not far advanced at present, in spite of spectacular development of noninvasive techniques.

The newborn brain is a different shape from the adult's: Frontal, parietal, and temporal lobes are relatively small. There is a conspicuous enlargement of the frontal region around the end of the 1st year. Measurements of head circumference apparently demonstrate significant age-related peaks of rate of growth at 3 to 4, 7 to 8, 10 to 11, and 15 to 18 weeks (Fischer & Rose, 1994). There are no other measurements that discriminate possible transitional events as well as these data appear to do.

Myelination studies show that some cortical and subcortical structures undergo extensive functional development. In the first 3 months, the greatest change is observed in motor pathways, sensory roots of the spinal cord, and visual projections to the midbrain tectum, thalamus, and cortex (Barkovich, Kjos, Jackson, & Norman, 1988). Subthalamic auditory pathways are more mature than visual ones at birth, but postthalamic auditory projections develop much more slowly than the visual over the first few years. Thalamocortical tracts for touch also develop slowly.

At birth, a rapid proliferation of dendritic branches of cortical cells and synaptogenesis, which began just before term, is continuing. After 3 months, growth of major dendritic branches ceases, but synapse density continues to increase until 6 months (Bourgeois, 2001; Huttenlocher, 1990). Synaptogenesis occurs at different times in different areas of the human cortex but is largely complete by the end of the 1st year. In the visual cortex, synaptic mechanisms of layer 4 neurons undergo rapid maturation at the same time as binocular stereopsis develops (Held, 1985; Held, Birch, & Gwiazda, 1980). The first 3 months is a time when sleep regulations that were set up prenatally, and associated processes of respiration and circulatory control undergo extensive consolidation (Kohyama, 1998). These changes are linked most obviously with developments in the body's motor capacity and in visual alertness and discrimination. The infant is becoming more open to the world and more adept at social exchanges.

It is likely that a large selective elimination of interhemispheric axons of the corpus callosum takes place during the first 6 months, before the callosal axons start myelinating (Innocenti, 1983). EEG coherence studies show that different corticocortical tracts between pairs of locations in the cortex are changing in their efficiency at particular ages,

and comparisons between locations in the two hemispheres indicate that cycles of development swing between left and right cortex throughout childhood (Thatcher, 1994).

PET scan evidence showing regional glucose utilization in infants' brains (H. T. Chugani, 1994, 1998) indicates that in the newborn in the primary sensory and motor cortices, thalamus, brain stem, and the vermis of the cerebellum are undergoing intense development, and the basal ganglia, hippocampus, and cingulate gyrus are also active. Parietal, temporal, and primary visual cortices, basal ganglia, and the cerebellar hemispheres are found to be developing during the first 3 months. The lateral and inferior frontal cortex shows increase of glucose consumption after 6 to 8 months, and the dorsal and medial frontal cortices show comparable increases only between 8 and 12 months. At 1 year, the infant's pattern of glucose utilization resembles that of an adult.

Foresightful Motives and Sociability: The Prefrontal Cortex

The *prefrontal cortex* (PFC) is now understood in cognitive psychology to be especially responsible for executive functioning, that is, with processes that program, control, and verify sensory information processing in the planning and organizing of behaviors (Figures 2.5 and 2.6). It is active in the selection or inhibition of specific behaviors, in initiating them and anticipating the effects. In short, from this perspective, the PFC performs complex cognitive functions integrating memory and imagination (D. A. Lewis, 1997). It is understood to have an essential role in the integration of information in future time (Fuster, 1989; Goldman-Rakic, 1987), a mastery of "time in the mind" (Pöppel & Wittmann, 1999) that accords with the close reciprocal anatomical relationship between the PFC and the cerebellum, which regulates the sensorimotor coordination of fast movements. The *dorsolateral PFC* is believed to retain transient memory traces that link the temporal discontinuities between recent events and future responses. The whole of the frontal part of the brain seems to "think ahead," and it is crucial for the integration and control of elaborate action plans and associated acts of selective attention and learning. But the *ventromedial PFC*, in association with the insula and limbic cortices, is also a regulator of *emotion* and of the motivation for efficient mental functioning in the pragmatics of social life, including the self-regulation of agency and *goal-directed activity*, *social self-awareness*, and *moral behavior* (Anderson, Bechara, Damasio, Tranel, & Damasio, 1999; Damasio, 1999; Damasio et al., 2000; Schore, 1994).

The frontal lobe undergoes important developments in infancy as a child becomes more active in collaborative awareness and learns to share meaningful experience with other persons (Diamond, 1991; Schore, 1994). In the last 3 months of the 1st year, when an infant is increasingly attentive to a parent's purposes (Hubley & Trevarthen, 1979; Trevarthen & Hubley, 1978) and performing expressive acts of protolanguage (Halliday, 1975), conspicuous developments in the prefrontal cortex correlate with advances in crawling and in the comprehension required for object-permanence tests of strategic attention, and for cognitive processes of executive intelligence (Bell & Fox, 1996). Evidently, brain mechanisms for action plans and locomotor maturation share common regulatory factors with motive systems that mediate in interpersonal attention and response to others' communicative expressions. Both phylogenetic and ontogenetic or developmental considerations would lead to the conclusion that this anterior part of the brain has evolved to integrate intrinsic emotional regulations with environmental information in the production of adaptive movements (Damasio, 1994; Luciana, 2001).

In the social world, the PFC appears to perform the most elaborate regulations of *expressive communication*. Complex cross-modal, or multisensory, integrations are required to match the underlying intentions and feelings in behaviors of other subjects (Diamond, 1990; Goldman-Rakic, 1987; Schore, 1994). In both monkeys and humans, parts of the PFC have a key role in the postnatal development of imitative communication skills, and in humans *Broca's area* mediates in the acquisition of all productive aspects of language, including speech (Damasio & Damasio, 1992). Research in monkeys has shown that the excitation of "mirror" neurons in frontal areas homologous with or adjacent to Broca's area "imitates" hand actions. Activation of these cells can specify either a gesture by the subject or visual perception of the same gesture in another individual (Rizzolatti & Arbib, 1998). They are part of what is now recognized as an extensive set of person-recognizing "sympathy" mechanisms distributed throughout associative and motivating regions of the cortex, including regions that mirror actions and others that are specifically involved in sympathetic reactions to visceromotor regulations and the emotional expressiveness of communication (Decety & Chaminade, 2003; Gallese, Keysers, & Rizzolatti, 2004).

Given the relative immaturity of the frontal cortex in early infancy, it is likely that unidentified subcortical motor mirror neuron components of a "sympathy system" are responsible for imitation in the 1st year, at least for the

many imitations of discrete and arbitrary expressions that neonates may perform. Mirroring actions involves trans-modal sensory recognitions, and there are many multi-modal neural populations in the brain stem, for example, in the superior colliculus and periaqueductal gray. These are integrated with systems that formulate motor images for action and expression (Holstege et al., 1996; Panksepp, 1998a). It should be recalled that lower vertebrates that lack a neocortex are capable of communicating by emitting and perceiving stereotyped motor routines (action patterns) that are made more salient by various signs stimuli on the body of the emitter (MacLean, 1990; Tinbergen, 1951). However, it has been demonstrated that regions of the frontal and temporal cortices that become essential for face recognition and for the understanding and production of speech in adults are already active in young infants when they are presented with a picture of a person (Tzourio-Mazoyer et al., 2002).

The frontal lobes depend on receptive and regulatory functions of other cortical regions and on extensive reciprocal relations with the brain stem emotional mechanisms (Schore, 1994). Structures that have a comparatively long development in humans and that are involved in the elaboration of new functions from fetal stages to adulthood include the reticular formation, hippocampus, dorsomedial temporal lobe, and parts of the cerebellum (Gilles, Shankle, & Dooling, 1983; Yakovlev & Lecours, 1967). These all mediate in collaboration between intrinsic motivating activities and acquisition of new organization under environmental instruction.

Children with Autism show abnormalities in the anatomy and function of PFC, as well as in medial temporal and parietotemporal cortices, which correlate with their difficulties in expressive communication and awareness of other persons' feelings and intentions (Dawson et al., 2002).

Sensing Others' Feelings and States of Mind from Their Movements and Building Memories of Relationships: The Temporal Lobes

Understanding others' speech and all other forms of communicative expression involves the *superior temporal cortex* (STC), the fusiform gyrus on the ventral surface of the temporal lobe, and the left temporoparietal cortex (Wernicke's area; Damasio & Damasio, 1992; Figures 2.5 and 2.6). Emotions of interpersonal awareness, which perform the essential regulations of affective and intersubjective contact, are mediated by the entorhinal cortex, amygdala, and hippocampus of the temporal lobes.

Development of *language* is governed by principles of perception and motor expression that motivate conversational interactions between infants and their parents (Trevvarthen, 1990, 2004b, 2004c, 2004d). Preverbal communication involves both limbic and neocortical mechanisms in temporal and prefrontal parts of the hemispheres, as well as many subcortical structures of forebrain, diencephalon, midbrain, and hindbrain. The *orbitofrontal cortex*, linked to the *medial temporal cortex*, has a key role in regulation of the balance between psychobiological state and transactions with the environment, including affective transactions with a caregiver (Field, Fox, Pickens, & Nawrocki, 1995), and it undergoes important elaboration in infancy (Schoore, 1994, 1998, 2001).

The hippocampal system (hippocampus, parahippocampus, entorhinal cortex, and perirhinal cortex) is important for forming a coherent set of memories of persons and social events and for recalling them in understanding engagements in the present (Cohen et al., 1999).

EARLY STRESS AND PSYCHOLOGICAL DEVELOPMENT: PROCESSES THAT CAUSE OR RESIST PATHOLOGY

We understand psychophysiological stress to be a product of the tension or balance between motive impulses to act on the environment and challenge it (*ergotropy*) and restorative processes that sustain vital integrity and capacity for action (*trophotropy*). The central nervous system, closely coupled to endocrine mechanisms that control essential cellular processes of organs that regulate the metabolism of the body and its internal environment, has a key role. It coordinates the balance of action and restoration and is itself both responsive to beneficial stimulation and vulnerable to excessive stress.

Developmental Neuropathology

Developmental psychopathology and developmental neuropathology have the task of explaining how the long and elaborate preparation for human intersubjective existence may go wrong at any stage of the formation of the brain's systems of motivation and prospective control of action, with the aim of improving both recognition and treatment of problems (Cicchetti, 1984, 1990; Cicchetti & Tucker, 1994).

Throughout the development of the brain, the balance of effects in a child's engagement with the outside world, and especially with other persons, determines the processes that promote further and more elaborate action and re-

sponse. Developments in the brain and body and in their genetic and epigenetic regulations undergo intrinsically regulated, age-related changes and respond to environmental stimuli and demands. Links between persons and their brains, mediated by transmitted effects of vital activities and movements of their different bodies, have importance at every stage.

Developing Autonomy in the Regulatory System of the Fetus and Coregulation before Birth

The ability of the embryo and fetus to respond adaptively to stress develops early in gestation. The most important parts of the future stress circuit, the hypothalamic region and the primordium of the hippocampus, are present in the human embryo at approximately 30 days after conception. Forebrain systems (such as the amygdala, stria terminalis) that will in future activate the HPA axis to socioemotional stressful events, are developing at the same time. The function of the HPA axis fluctuates throughout pregnancy, with a temporary suppression period in midpregnancy.

After early fetuses react to sensory stimulation around the 7th week of gestation, repeated stimulation results in an apparent hyperexcitability. This might correspond more with the development of the motor capacity of the fetus than with any experience of pain. It is also possible that the brain may react to stress earlier, when movements cannot occur. From the 16th week of gestation, increased blood flow in the fetus has been shown to follow invasive procedures (Teixeira, Glover, & Fisk, 1999), and from the 18th week, a rapid increase of the level of noradrenaline and a slower increase of the cortisol and beta-endorphin indicate the presence of a fully functioning stress response to painful invasive procedures (Gitau, Fisk, Teixeira, Cameron, & Glover, 2001). Fetuses show complex reactions to noxious stimuli long before there are thalamocortical projections to the cortex at around 26 weeks, and these reactions include stress responses that are likely to affect development (Vanhatalo & van Nieuwenhuizen, 2000).

Stress responses of the mother lead to increased glucocorticoid levels by activation of her HPA system. The fetus, however, possesses protective mechanisms to filter the effects of maternal hormones. The placenta can block the transport of glucocorticoids into the fetal circulation, partially protecting the fetus from the maternal stress response (Jones, 1993). The 11-beta-hydroxysteroid-dehydrogenase enzyme of the fetus provides another level of protection by breaking down the cortisol to inactive cortisone.

Higher circulating cortisol level leads to the HPA axis becoming suppressed to prevent the production of further

cortisol, which could be damaging to the organism. However, between the 18th and 40th weeks of gestation, the negative feedback from the circulating cortisol to the HPA axis is itself reduced, which means that a high level of glucocorticoids could in fact have negative effects on fetal growth and development as the fetus opens this potential transmission of strong effects from the mother.

Although the level must be modulated, prenatal exposure to glucocorticoids in the fetus is necessary for normal growth and development. The production by the placenta of the 11-beta-hydroxysteroid-dehydrogenase enzyme, which protects the fetus from the high level of glucocorticoids, is in fact regulated by the maternal glucocorticoids. This collaborative regulation is one of the most important mechanisms to protect the fetus from too high levels of maternal glucocorticoids (van Beek, Guan, Julian, & Yang, 2004). The same enzyme is important in the development of surfactant in the fetal lung, the compound that makes the lung surface able to absorb oxygen and thereby makes the fetus independently viable (Hundertmark et al., 2002).

Measurement of fetal heart rate (FHR) acceleration to vibroacoustic stimulation (VAS) can be used from week 28 to detect the capacity of the fetus to respond and to self-regulate (habituate; Groome, Bentz, & Singh, 1995; Hepper, 1995). VAS by a vibrator applied to the mother's belly, though artificial, might be considered to act like a mother's voice to attract the readiness of the fetus to engage with her. There appears to be a change after 32 weeks, when VAS causes FHR deceleration, possibly indicative of a new alerting response (Jensen, 1984). The subthalamic brain stem auditory system is well-developed from the second trimester. Maternal emotional state can have effects on the fetal response. Fetuses of depressed mothers, but not those with anxiety disorders, have a higher baseline FHR, show a greater response to VAS, and return to their baseline levels more slowly (Allister, Lester, Carr, & Liu, 2001; Monk et al., 2004).

Winnicott (1960) identified a "primary maternal preoccupation" of expectant and new mothers. Pregnancy is associated with a dampening of the mother's physiological reaction to stressors or exercise and a temporary reduction of cognitive capacities (Barron, Mujais, Zinaman, Bravo, & Lindheimer, 1986; Buckwalter, Stolley, & Farran, 1999; deGroot, Adam, & Hornstra, 2003; Kammerer, Adams, von Castleberg, & Glover, 2002; Matthews & Rodin, 1992). All these changes reflect sympathetic activation of the mother by the fetus.

The fetus is an active agent (Smotherman & Robinson, 1987) and can stimulate labor (Challis et al., 2001). DiPietro et al. (2004, p. 518) offer evidence that the relation-

ship between the fetus and mother is bidirectional from the start, and they propose that the capacity of the fetus to influence the mother's psychophysiological state from midgestation has been underestimated: "The observed phenomenon of maternal sympathetic activation by the fetus may serve a signal function to the pregnant woman in preparation for the consuming early demands of child rearing and redirecting maternal resources directed at competing but less relevant environmental demands." Moreover, the same research group (DiPietro, Hodgson, Costigan, Hilton, & Johnson, 1996) found that a stable synchrony of regulation is characteristic of individual maternal-fetal pairs. A mutually adapted pair of individuals forms a *single integrated system* with its own synchrony.

The Relationship after Birth

Clearly, the mother-child mutual regulation is active and functioning to assist development before birth, but all systems that have been linking a developing embryo and fetus with regulatory systems of the mother's body are transformed after birth by maturation of *attachment systems* that sustain parental care and that lead to the development of regulations of emotional companionships and shared activity that will foster the learning of knowledge and skills throughout life. The "evolutionary based dyad" of the mother and the infant (Dugdale, 1986) provides a level of protection against the negative effects of the glucocorticoids on the developing brain, just as close contact between the mother and the rat pup lowers the reactivity of the HPA axis of the pup to stressful events (Suchecki, Rosenfeld, & Levine, 1993), and offspring of more experienced rhesus monkey mothers show significantly reduced stress response and cortisol level (Kalin, Larson, Shelton, & Davidson, 1998). Evidently, rhesus mothers learn from their offspring to be better regulators of future juveniles.

The human mother's role in buffering physiological stress responses is demonstrated by a study of 18-month-old infants' cortisol levels when they were approached by a stranger in the presence of their mother; infants with secure attachment did not show a rise, but others who were insecurely attached did show a significant cortisol elevation (Gunnar, 1998). Salivary cortisol levels of human infants awaiting inoculation did not rise if the child was left with a friendly and sensitive babysitter compared to an unfriendly and insensitive one (Gunnar, Larson, Hertsgaard, Harris, & Brodersen, 1992). Evidently, the relationship with the caregiver can provide a powerful "sociobiological buffer" or psychobiological coregulation for an infant. Reduction in the level of cortisol indicates a more effective

down-regulation of the stress process by the hippocampus and the prefrontal cortex (Schoore, 1996, 2003a, 2003b).

Stress and Early Psychopathology

Although abnormalities in the motivating and emotional systems in the embryo brain are mainly of genetic origin (Lyon & Gadisseux, 1991) or caused by severe pathogens interfering with the action of genetic mechanisms, there is little evidence for simple, consistent effects of mutations in single genes. None of the developmental psychopathologies of socioemotional life that are recognized in diagnostic systems, including dyslexia, specific language impairment, Autistic Spectrum Disorders, and Attention-Deficit/Hyperactivity Disorder (ADHD), appears to be a direct effect of an inherited genetic fault (Dawson et al., 2002; Tager-Flusberg, 1999; Trevarthen, 2001b). All reflect the cumulative effect of stresses and traumas that interfere with the expression and development of inherent capacities to form relationships that benefit self-motivations and their development (Cicchetti & Dawson, 2002; Cicchetti & Rogosch, 1996). It follows that any psychopathological conditions, and perhaps all, may be susceptible to amelioration by adjustment of the demands of the environment, especially, in many cases, by transforming the quality and availability of human care and support—that is, by forms of treatment that act through the intersubjective route rather than, or in addition to, direct interventions with intraorganismic functions by chemical means. Communicative interactions may rebuild vital functions and self-regulatory states, mitigating the effects of early stress and posttraumatic disorders later in life.

Damage to the brain in early stages of development, especially in sensitive periods, may be linked many years later to unusual sensitivity to trauma and may be a cause of psychopathology of understanding and behavior that appears as a new problem in a child or adult. There are clinical studies indicating that prenatal stress is associated with development of ADHD in children (Weinstock, 1997). Evidence from the self-regulatory and socioemotional problems of adolescence indicates that all levels of regulation, from the physiological to the social, can carry problems from infancy that emerge in this critical period of life when the brain is undergoing a second period of accelerated growth and differentiation in adaptation to changing interpersonal and social circumstances (Cicchetti & Rogosch, 2002).

Schizophrenia is associated with pregnancy and birth complications (Stefan & Murray, 1997), and mothers of schizophrenic patients suffered more often from severe in-

fections during pregnancy, possibly affecting cytokines and indirectly the development of monoaminergic circuits in the fetal brain (Jarskog, Xiao, Wilkie, Lauder, & Gilmore, 1997).

Increased Reactivity of the Brain Following Stress to the Fetus

Stress during critical periods of intrauterine development of mammals alters the brain's biochemistry as a result of activation of the ANS (Davis, Suris, Lambert, Heimberg, & Petty, 1997; de Kloet et al., 1996; J. P. Henry & Stephens, 1977). Biochemical changes following release of stress hormones are manifested by structural and metabolic alterations in specific areas of the brain (Bremner, 2002; Sapolsky, 1996). Cortical thickness may be reduced in regions important for functions of emotion and memory. Stress is also associated with reduced neuroplasticity, and this later facilitates the development of psychopathological conditions and functional disturbances that are difficult to characterize within standard medical and psychological criteria or diagnostic classification systems for psychological disorders. Fetal brain development is changed and may be retarded by high levels of maternal stress hormones (Glynn, Wadhwa, & Sandman, 2000). This can be reflected in premature delivery or low birthweight for gestational age and smaller head circumference (Hedegaard, 1999; Huizink, Mulder, & Buitelaar, 2004).

The concept of “fetal and neonatal programming” (Sayer, Cooper, & Barker, 1997) also applies to the ontogeny of the neurochemical system (Herlenius & Lagercrantz, 2004). Prenatal or perinatal stress can disturb the timetable of the expression of neurotransmitters and neuromodulators and their receptors (Johnston, 1995).

Disruption of the normal timing or intensity of neurotransmitter signaling can lead to permanent changes in proliferation differentiation and growth of their target cells during critical phases of development of the nervous system, thereby possibly providing the underlying mechanisms for neurobehavioral or neurophysiological abnormalities associated with developmental exposure to neuroactive drugs and environmental toxins. (Herlenius & Lagercrantz, 2004, p. S18)

Research on animals has shown that brain areas dense in glucocorticoid receptors, such as the hippocampus, prefrontal cortex, and septum pellucidum, respond with structural changes even to a very brief exposure to a stressor. Dendrites of the pyramidal neurons in the CA3 region of the hippocampus become shorter, with fewer branches, and the production of the granular cells will be reduced (McEwen,

1999, 2001) as a response to the increased level of glucocorticoids. High levels of prenatally administered dexamethasone (a cortisol derivative) in monkeys cause cell death (apoptosis), with an approximately 30% reduction of the volume of the hippocampus; this structural change is detectable even at 20 months after birth (Uno et al., 1994). Corticosteroids have deleterious effects on the brain and behavior of developing primates, causing inhibition of neural stem cells, neurogenesis, and migration and leading to irreversible decrease in brain weight (Edwards & Burnham, 2001; Matthews, 2001).

Prenatal stress can also cause changes in the structure of the corpus callosum, and the hemispheric laterality can be modified. Handedness in rhesus monkeys can be associated with the level of stress reactivity (Westergaard, Byrne, & Suomi, 2000). Atypical asymmetry of the dopaminergic pathways in the prefrontal cortex as a response to prenatal stress can lead to behavioral inhibition, disturbances of working memory, or inattention, and children with ADHD have been reported to exhibit an increased left prefrontal activity dominance instead of the right dominance typical of children without ADHD, that is, a deficit of right hemisphere attention and motor control (Castellanos et al., 1996).

The effects of stress hormones on affective and cognitive functioning vary, and not all are damaging (de Kloet, Oitzl, & Joels, 1999; McEwen, 1997b, 2003; Roozendaal, de Quervain, Ferry, Setlow, & McGaugh, 2001; Vandekerckhove, in press). Depending on the intensity and duration of stress, the effects may be beneficial or destructive to the adaptive functions of the developing brain and in behavior: *Brief* periods of stress can potentiate psychological functions, such as memory formation, whereas *chronic* or sustained *high-intensity* stress may disturb the brain to the extent of a total blockade of the retention of experience by the brain ("mnestic block syndrome"; Markowitsch, Kessler, Kalbe, & Herholz, 1999; Markowitsch, Kessler, Russ, et al., 1999). On the neuronal level, *moderate* duration of stress causes reversible atrophy of apical dendrites on pyramidal neurons, but basal dendrites remain unchanged. Thus, chronic stress is more dangerous than acute stress for the young brain (Garmezy & Masten, 1994). Prolonged high concentrations of glucocorticoids may lead to suppression of the immune system, hypertension, an altered vesicle distribution pattern in the brain, and irreversible brain cell death (Maccari et al., 2003; Magarinos, Verdugo, & McEwen, 1997; Sapolsky, 1993, 1996, 2000).

In rats, unpredictable stress during gestation (such as repeated loud and unanticipated noises) increases fear responses of pups, and the effects may be expressed in adult

animals as behavioral problems in conflict-rich situations (Fride & Weinstock, 1988). The affected rat pup is more easily frightened, while exhibiting less exploratory behavior and heightened tendencies of behavioral and social inhibition (Fride & Weinstock, 1988; Maccari et al., 2003; Takahashi & Kalin, 1991).

Short prenatal exposure of the sheep fetus to cortisol at the end of the 1st month of gestation (considered a critical stage of development) programmed high blood pressure in the adult female and male offspring, and there were effects on regulation of gene expression in the hippocampus (Dodic et al., 2002).

A longitudinal study examining prenatal disturbance in about 10,000 women demonstrated that anxiety in late pregnancy increased behavioral/emotional problems in the child at 4 years of age (O'Connor, Heron, Golding, Beveridge, & Glover, 2002). Similarly, mothers' prenatal and postnatal stressors are correlated with temperament of their 3-year-olds (Susman, Schmeelk, Ponirakis, & Gariepy, 2001). In a population-based study of more than 3,000 women in Copenhagen, of which 70 were identified as experiencing moderate to severe stressful life events and compared with 50 nonstressed women with an intact social network, found that stress and smoking adversely affected birthweight and head circumference. The findings support the concept of a *fetal stress syndrome* with adverse effects on fetal development, including deficient brain development (Lou et al., 1995).

The fetus and the newborn react differently to various forms of stress. In general, fetuses tend to react by immobilization, decreased heart rate, and decreased breathing, with slowed metabolism caused possibly by inhibited neurotransmission (Lagercrantz, 1996). Neuromodulators, such as adenosine, neuropeptide Y, somatostatin, and opioids, may mediate this effect. At birth, the increased somatosensory input, increased level of arterial oxygen, and mechanical stimulation of the baby results in a down-regulated inhibitory and up-regulated excitatory neurotransmitter level in the brain mediated by the increased expression of the immediate early genes (Ringstedt, Tang, Persson, Lendahl, & Lagercrantz, 1995).

Stress Effects on the Brain after Birth

Prolonged and repeated separations from a contact-averse, nonattuning mother may cause an infant to develop a state of enhanced corticotrophic activity, sympathetic-dominant agitated hyperarousal, and general hypervigilance for critical information (Perry, Pollard, Blakley, Baker, & Vigilante, 1995). Field and coworkers (Field, 1998, 2005; Field et al., 1988) found that infants of de-

pressed mothers vocalized less, displayed increased gaze aversion, fussiness, and helplessness, and at the same time had higher heart rates and decreased vagal tone. They also show delays in growth and development at 12 months of age (Field, 1995, 1998). Dawson and her colleagues (Hessl et al., 1998) have reported slightly higher midmorning cortisol levels at home among 3-year-old children whose mothers were clinically depressed compared to children of emotionally healthy mothers. Neurophysiological signs, such as elevated salivary cortisol and disturbed sleep, might be important early indicators of risk for the development of psychopathology for children who show no clear manifestations of distress in their behavior.

The developing intelligence, memory, and imagination of a child transforms the effects stress can have in the brain and on the mind and may bring new disorders that affect life with other human beings. The classical physiological understanding of stress focuses on the peripheral neuronal and hormonal mechanism and neglects the role of the central nervous system (Dunn et al., 2004). Many neurochemical changes occur in the brain itself during or after various forms of experimental stress, notably the activation of cerebral catecholaminergic systems. Activation of cerebral noradrenergic neurons may represent a central counterpart to the peripheral ANS activation. Dopaminergic and adrenergic systems also respond, as well as endorphin systems and CRF-containing neurons. Thus, stress-related events in the CNS appear to parallel those in the periphery. The down-regulation of adrenergic receptors that occurs in chronic stress presumably represents an adaptation of the brain to deal with excess norepinephrine (NE) release, and this could explain the behavioral adaptation.

NE is known to play a role in regulating cerebral blood flow and perhaps regulates blood-brain barrier permeability. The noradrenergic projections from the locus coeruleus to the forebrain have been shown to cause the cortical desynchronization associated with arousal, and it has been suggested that this enables selective attention to novel stimuli by decreasing signal-to-noise ratios for the responses to such stimuli. NE has been postulated to play a role in neuroplasticity and has long been implicated in higher nervous functions such as learning and memory. The CRF family of peptides appears to play a critical role in anxiety and/or stress responses.

Posttraumatic Stress Disorder is the most deeply destructive consequence of severe stress on brain function; PTSD is a “physioneurosis,” a mental disorder based on the persistence of biological emergency responses (van der Kolk, 2003), affecting the limbic structures that govern the

most basic social responses (MacLean, 1990). As a traumatized child grows older in a disorganized, high-stress environment, he or she might encounter traumatic situations or trauma-related narratives. When older children are exposed to stimuli that are associated with or that remind them of the original trauma—witnessing violence, being abused, or being kidnapped—critical neural pathways related to the previous experience of the threat might become reactivated, and the children may be prone to symptoms of PTSD, including poor impulse control, self-destructive behavior, phobias, anxieties, and depressive states (Cicchetti & Toth, 2000; Cytryn, McKnew, & Bunney, 1980; Kendall-Tackett, Meyer-Williams, & Finkelhor, 1993).

Traumatic memories are characterized by retention of sensory and emotional impressions that are stable and unalterable and that are likely to return vividly throughout life if triggered by reminders. The victim cannot articulate the feelings and thoughts brought back and cannot formulate a “storyline” for experiences. Such problems seriously impair the ability of a child to engage in sustained activities without distraction or to learn a range of alternatives without being disorganized or acting too impulsively on one of them. Both compliance with complex social rules and understanding of schematic representations of reality are impaired. There is evidence of atrophy of specific brain regions, in particular the hippocampus and the amygdala, which are important in cognition, memory, and emotion, and a heightened vulnerability of the self (McEwen, 1999; O’Keefe & Nadel, 1978; Starkman et al., 1999). In response to frequent chronic or massive stress situations, both children and adults may display significant reductions in emotional and social processing, in ability to learn, and in perceptual, intellectual, and memory capacities (van der Kolk, 2003).

Attachments and Shared Experience in Infancy and How Dysregulations of Interpersonal Regulations Affect Human Learning

In the half-century since Bowlby (1958) presented his theory that the infant is born with innate behavior-releasing mechanisms adapted to engage with and attract care from a loving mother, a great body of research has confirmed his insight. He was finding an explanation for the withdrawal and despair he saw in infants and toddlers who had been orphaned by war and similar behavior of infants separated from their mother for hospital care (Bowlby, 1969). There was, however, skepticism from both medical and psychological professions at first, both doubting that human nature could be so complex at birth, and that there was a

specific and exclusive need for the biological mother was “disproved.”

In recent decades, Bowlby’s ethological model has been extended by the findings of psychobiological research on mechanisms that cause a rat pup or nursing monkey to express distress when isolated (Hofer, 1987; Kraemer, 1992). The benefits to the physiological systems of the offspring of maternal stimulation that regulate neurohumoral stress reactions have been proved. An emphasis has been placed on the plasticity of the infant brain and on the mother as a regulator of states of motivation that affect function and growth of brain structures that are critical for future regulation of social emotions and learning. In both Bowlby’s ethological attachment theory and the new psychobiological attachment theory of stress regulation, the task of the newborn mammal is to commence a process of internalizing a module: a cognitive internal working model of the mother as a support for living in the world, or an internal regulator of stress-resisting neurohumoral states.

Bowlby’s theory was made empirically testable by Ainsworth’s Strange Situation (Lamb, Thompson, Gardner, Charnov, & Estes, 1984). Consistent differences were found between groups of 1-year-olds who were subjected to this temporary stress in the absence of their mother and then reunited with her. The classification of different attachment types—A (avoidant), B (secure), and C (resistant; Ainsworth, Blehar, Waters, & Wall, 1978)—was extended by identification of a seriously disturbed D (disorganized) group (Main & Solomon, 1986). In correlation studies to detect relationships between these infant attachment groups and mother’s behaviors in populations, highly significant consistencies and some systematic cultural differences were found between maternal characteristics and their infants’ approach behaviors and emotional signals toward them in the Strange Situation. The basic assumption has been that these correlations represent effects of maternal care on the development of regulatory “representations” of emotions and investigative impulses in the infant.

Now the weight of evidence is showing that infants have more complex and more variable volitions and emotions and much richer inherent capacities to perceive the motives of companions—that they play an active “mothering-expectant” part from birth in eliciting and regulating maternal behaviors. A healthy baby is, from the start, also adapted with motives for building joyful shared experience in play, with seeking emotions that explore the world with all sense, in addition to the need for receiving regulation of autonomic and HPA states and protection against brain damage from the effects of cortisol.

Because the dispositions of an infant at birth depend on unique paths of prenatal maturation of motives for both mutual regulation of vital state and stress control and motives for gaining experience from exploratory activity, there are emerging individual differences in personality, temperament, and cognitive development between children, which are affected by many prenatal factors, from genes to the nurturant support and physiological health of the mother’s body. The rich variety of responses and initiatives observed in a detailed neonatal assessment (Brazelton & Nugent, 1995) proves this variability of potential in human nature at birth. A distinction must be made at the two extremes, between psychopathologies that may afflict the life of children when they are severely mistreated by neglect or abuse, and when in addition they lack adequate present psychosocial support (Lyons-Ruth, Connell, Grunebaum, & Botein, 1990), from those differences, evident in different ways at different ages, but already detectable in neonates or even before birth (Field, 1985; Piontelli, 1992), in self-confidence, adventurousness, and sociability. These should be seen as variations in adaptive motives for sustaining collaborative relationships and forms of mutual emotional support in the full course of each life.

A model is required that grants the infant a brain organization that can anticipate and immediately recognize human company in complex dynamic ways—an intersubjectivity system that is ready for intense intimate exchanges with a wide range of caregivers’ states of emotional availability and willingness to share activities (Aitken & Trevarthen, 1997). Functional imaging of activity in the brain of an infant that reflects awareness of another person, as well as a fund of evidence from developmental brain science, confirms the existence of such a mechanism (Tzourio-Mazoyer et al., 2002), one evolved from the affective neural systems that regulate social encounters and cooperative behaviors in other vertebrates (MacLean, 1990).

Evidence from psychophysiology, developmental brain science, and genetics concerning how the infant-caregiver system may work to support growth of this complex endowment for regulation of intermental life and for collaboration in conscious voluntary activities converges to support the idea that there is an adaptive mutual regulatory system for *interest and purposes* and one for *affective interpersonal emotional states* that assess and direct the subconscious relationship. Developmental studies of age-related changes in normal development of securely supported infants prove that the infants’ motives and the caregivers’ responses are aimed, together, toward the goal of having compatible experiences so the child can acquire both a well-received and

happy social personality and culturally valued knowledge and skills (Trevarthen, 2005b, 2005c).

By enriching both the situations for observation of behaviors of parents and infants and their siblings, or of infants in peer groups and in groups of children and a range of other adults inside and outside the family, and by more sensitive analysis of forms of behavior and their functions, it has been made clear that infants are truly sociable. They seek to form friendships, to protect themselves from being misunderstood and intruded upon, and to learn in "intent participation" with others in games where meanings for actions and objects are fabricated, tested, and learned (Fiammenghi, 1997; Nadel & Tremblay-Leveau, 1999; Selby & Bradley, 2003). They can cope in communication with several members of the family at once (Fivaz-Depeursinge & Corboz-Warnery, 1999; Hay, 1985).

Maternal health is critically important for these needs for sociability, of course. Bowlby was not wrong in giving the mother a privileged place, a place prepared for by the events of her pregnancy when her stimulation of and responses to her infant were already building a relationship. But the developing child is adaptable for more than one relationship, and the place of a mother can be taken by someone who is ready to build a new relationship of intimate familiarity and responsivity, one willing to pick up on the infant's capacities for regulating both self and a companion.

If the infant is in the care of a mother who has significant *clinical postnatal depression* (PND) and no other person can replace her, this is likely to depress the infant, reducing the capacity to develop self-regulation and enjoyable play with a parent (Beebe et al., in press; Field, 1984, 1992, 2005; Field et al., 1988; Murray, 1988, 1992), and in some cases the effects persist to compromise a child's capacities to take an active part in a wider social world and to profit from education (Hay & Kumar, 1995; Murray & Cooper, 1997; Murray, Woolgar, Briers, & Hipwell, 1999). However, it is also true that infants born irritable and difficult for a mother to relate to or care for, and who exhibit differences in neonatal assessment, can predispose a mother to PND (Murray, Stanley, Hooper, King, & Fiori-Cowley, 1996). PND affects all aspects of a mother's expression of affection for and interest in her infant: her holding, her attention to her infant's interests and emotions, the emotions in her voice, her responses to calls for care or for play, in addition to her capacity to give psychobiological support (Bettes, 1988; Breznitz & Sherman, 1987; Murray, Kempton, Woolgar, & Hooper, 1993; Reissland, Shepherd, & Herrera, in press-a, in press-b; Robb, 1999; Tronick & Weinberg, 1996).

The liveliness and availability of a mother is affected by her social situation, security, and relationships with the father or other partner and the wider family. Recollections from her own childhood influence how she sees the baby (Main & Goldwyn, 1984). The cultural context for mothering has powerful effects; this is a factor that gives cause for concern in the unstable present state of human communities (Nugent, 2002). A migrant mother displaced from her extended family and, perhaps most important, separated from her own mother may also be unable to respond to her infant and participate in well-regulated playful communication with shared pleasure: The experience of *belonging* is of fundamental importance (Gratier, 2003).

PTSD is a serious threat to the mother-infant system and a cause for special attention (Schechter, 2004). A woman who has experienced trauma, including abuse when a child, may find her infant's expressions of need frightening. They may precipitate pathological anxiety and emotional instability that can lead her to be insensitive or abusive to her child. An infant in the care of a mother suffering PTSD is at risk of developing frantic attempts to find contentment and disorganized attachment (Ornitz & Pynoos, 1989; Pollak, Cicchetti, & Klorman, 1998), which predisposes the child to develop serious emotional problems later in life, with the parent or in adoption. A cycle of fear and confusion can develop that disrupts all attempts of the family to function as a mutually supportive group (Archer & Burnell, 2003).

Despite the abundant evidence that childhood psychopathology can be related to emotional illness in the mother, the recognition that there is a strong set of adaptations in an infant to solicit, relate to, and benefit from communication with other persons helps explain the evidence that even badly neglected and mistreated infants can demonstrate impressive resilience and rediscover a path in childhood, adolescent, and adult relationships that is rewarding and productive of a proud life story (Luthar, Cicchetti, & Becker, 2000; Masten, 2001; Rutter, 1987; Sander, 1964).

Methods of molecular genetics have enabled researchers to discover factors that explain infant self-regulatory and behavioral differences and communication, as well as the different ways adults regulate their relationships with infants. Male and female infants differ in their psychologies and communicative behavior, as do the parenting behaviors of mothers and fathers. The differences between infants affect their expressions of sociability and sharing of interest in object-directed activities. In toddlers, these differences appear to be significant in social experience and learning with peers. These differences

cannot all be explained as consequences of cultural beliefs and practices that lead to different treatment of boys and girls. It has been mentioned that seeking genetic explanations for such differences in motivation or temperament is complicated by clear evidence that epigenetic factors usually make the personalities of homozygous twins different (Piontelli, 2002). Whatever effect genes have in determining differences between male and female infants, or between those of the same sex, they will be mediated by differences arising in the hormonal systems that regulate sexual and other differentiations of bodies and brains both before and after birth. Male infants show a greater susceptibility to disturbance of their development by interpersonal stresses, including being in the care of a mother with PND (Murray et al., 1993).

It has been emphasized that confusion in the literature concerning genetic factors certainly arises from a failure of many studies to give sufficient attention to powerful interactions between socioemotional or ecological factors and the expressions of gene-related changes in basic regulatory mechanisms. None of the neurohumoral stress-regulating systems and none of the neural systems of emotion is insulated from changes due to environmental circumstances. These have evolved both to regulate and to be regulated by the risks and benefits of the behaviors they control.

In summary, a baby with neurohumoral systems of self-regulation that are partly protected from effects of stress in the caregiver's life is born ready to be actively part of intimate human relations that are regulated by sympathetic tenderness and the vitality of play (Veldman, 1994). The development of this system of mutual regulation depends on the availability and vitality of adult care, and thus on the situation of the family in relation to the wider society. Infants need available, regular, and responsive company, and all these can be weakened by fear and deprivation in the community where the caregivers make their lives. But the infant is resourceful, and some, at least, can protect themselves when parental care is deficient in sensitivity but adequate for survival. With good fortune, a young infant becomes a catalyst to a better life for the family and not an extra burden to carry (Gomes-Pedro, Nugent, Young, & Brazelton, 2002).

Especially poignant are the life stories of children who, because their biological parents have neglected or abused them, or because their homes and families have been destroyed in violent circumstances, are taken into foster care or adoption. Adoptive parents are often couples who have had a long, difficult period of waiting for children of their own. They undertake to care for and support the development of damaged children who are confused, fearful, and

angry, carrying memories they can regulate in no other way. The experience of the adults and the children, and of the social services and clinicians who support their efforts to find relief from stress and a happy future, can teach much about the fragility and resourcefulness of human motives and the regulation of feelings and new experiences in attachment relationships (Archer & Burnell, 2003; Hughes, 1997, 1998).

FUTURE DIRECTIONS FOR INFANT MENTAL HEALTH: FOSTERING MOTIVES FOR CONFIDENT REGULATION OF EXPERIENCE IN AFFECTIONATE COMPANIONSHIP

In the case of an animal, the mental states enter into the plan of the total organism and thus modify the plans of successive subordinate organisms until the ultimate smallest organism, such as electrons, are reached. (Whitehead, 1926/1953, p. 98)

There are thus two sides to the machinery involved in the development of nature. On the one side there is a given environment with organisms adapting themselves to it. . . . The other side of the evolutionary machinery, the neglected side, is expressed by the word creativeness. *The organisms can create their own environment. For this purpose the single organism is almost helpless. The adequate forces require societies of cooperating organisms.* But with such cooperation and in proportion to the effort put forward, the environment has a plasticity which alters the whole ethical aspect of evolution. (Whitehead, 1926/1953, p. 140; emphasis added)

Mutual Regulations and Change in the Mother-Child Relationship

We focus our analysis of early psychosocial development and its emotional regulations on the side of the "machinery of nature" that Whitehead calls creative. We have defined two levels of mutual regulation in the development of a human mind that function from prenatal stages, both of which undergo major developments in infancy. We propose that recognition of these is essential both for understanding and diagnosing causes of psychopathology, for developing helpful parental support, for improving social support for the families, and for corrective treatments to counter risks of future psychopathology due to stress.

The *amphoteronomic* level brings the life systems of two organisms and their individual autonomic regulations into a mutually beneficial relationship that accomplishes more than either organism can do on its own. In the case of a human fetus, the growing organism is inside the mother's

body and connected to her through tissue frontiers that exercise control over the passage of substances between them (Figure 2.7).

The placenta (Figure 2.8) is the main collaborative organ at this stage (Jones, 1993). It conveys essential nutrients and oxygen to the fetus and takes out CO₂ and other waste. For other substances, the placenta is highly selective and acts as a barrier to the large molecules that serve as hormones in the separate autonomic regulations of both fetus and mother (Figure 2.7). The developing autonomic system (HPA, SNS, and PNS) of the fetus, with the neurochemical transmission systems that mediate between their relations with the developing sensorimotor organs of the fetal brain, act as an increasingly competent regulation for the fetus itself, but there are essential interactions with the mother, which we have reviewed here.

The *synrhythmic* level of regulation comes into full effect after birth. It couples the volitional and experiential functions of the minds of infant and mother through sympathetic response of their brains to the anatomical forms and dynamics of movement in structures of the body activated by the special visceral efferents of the cephalic SNS (Figures 2.6 and 2.7). The frontier for this regulation is in the living socioemotional space between the expressive actions of the two human beings and their minds (Figure 2.12). The efficiency of mutual psychological engagement at birth can be seen when an alert newborn free of distress is in reciprocal imitative contact with a mother or other sensitively responsive and patient adult.

We find evidence that the beginning of synrhythmic regulation begins earlier, at least by the beginning of the last trimester of gestation. In this period, mother and infant can interact not only by hormonal amphoteronomic means, but

also by tactile, auditory, and vestibular stimulation of the fetus from the mother's body displacements, uterine contractions, and vocalizations and by the mother receiving stimuli from periods when the fetus is active and making limb and body movements (Veldman, 1994). Their cycles of activity interact and may become mutually entrained. This minimal communication of activities is assisted by amphoteronomic hormonal coupling, for example, by the passage of melatonin from the mother to the fetus, which helps synchronization of their day-night cycles.

At term, the fetus is expectant of a much richer traffic across the synrhythmic frontier with the mother, traffic that will be carried by an intensely active and rapidly developing visual system, as well as by the more precociously developed systems of touch and hearing. This regulation of *emergent intermental or psychological capacities* complements new amphoteronomic regulations between mother and newborn made active in breast-feeding and other caregiving activities, which are mediated by sensations of taste, olfaction, and body contact on both sides.

Synrhythmic regulations undergo conspicuous developments after birth as all modalities and new motor capacities become active in engaging motives and emotions between the infant and caregiver (Figure 2.9). We see the development of intimate protoconversations at 2 to 3 months and more testing negotiations of play and affectionate teasing from 3 months as preparatory for the person-person-object games that emerge after 6 months. These, in turn, are predictive of competence in the infant for acquisition of knowledge and skills concerning the uses of familiar objects that frequently occupy the interest of the infant's companions and for the imitation of words to name the more significant and sharable things and actions. This introduces a sociocultural level of regulation that begins the education of the child in meanings that have become essential to the life of a large society and its artifacts. We have not contrived a word for the regulation of this level, which falls outside the period of infancy, but the word "symbolic" conveys the sense of its essentially sociocultural nature.

The core of our account is that human psychological development begins in coregulated vital and volitional relationships that make significant changes to the power of communication before language begins. We affirm that support of this coregulation is critical for infant mental well-being. The basic concept is one of an agency-generating and stress-controlling system *between* two organisms, the developing child and the mother, who, for at least half of the period we have considered, is the sole partner of the infant in mutual development.

Figure 2.12 Protoconversation between mother and infant. *Synrhythmic* regulation of mutual psychological engagement by exchange of expressions of interest and emotional feelings.

Theories of Infant Mental Health and Its Needs and Risks

The past century has seen significant changes in the concept of the infant mind and *infant mental health*, concepts that can be said to have not existed at all in most of the early decades of this time (Fraiberg, 1980). It is still the case that developmental and medical scientists question the idea that a young infant has mental capacities. There have also been changes in the kinds of society that children are born into. It is likely that the threats to the well-being and sanity of young children are greater than a century ago. Certainly, a large proportion of the world's families are struggling with hunger and dangerous situations, and their children are at risk of developing socioemotional illness later in life and, in consequence, contributing to the hardships of the community—all these problems being not least in the richest countries (Brazelton, 2002). The threatened families live in communities that lack appropriate human support for their infants and for their mothers (Gomes-Pedro et al., 2002; Raphael-Leff, 2005).

It would appear urgent for medical attention to be given to more than the diagnosis and treatment of disorders of early development that have identifiable physiological, neurological, or molecular causes (or correlates), to accept remedies that are based on acceptance that the child is a source of regulatory principles that can benefit not just the body and mind of the mother, but the family and society. Children activate intrinsic forces of emotional and behavioral self-regulation in adults and their collaborative systems and organizations. But these social systems and organizations tend, by their own autopoiesis, to become endlessly extended and elaborated and overly complex in the sense that they cease to work in a creative way, like the excess of components that proliferate in the neocortex before motivated experience has pruned them. We need, perhaps, a selective apoptosis of laws, institutional management, and curricular goals to potentiate this source of social well-being. This will have to be guided by respect for the inherent motives and sympathies or “developmental principles” (Bronfenbrenner, 2002) that create human knowledge and collective understanding, not by even more quick-fix draconian measures for “national security” or “prosperity,” which, driven by an excessive political anxiety, promote division and mistrust in communities and weaken families, as well as threatening the balance of relationships between human communities and the natural world (Gore, 1992).

There is abundant evidence of the damage done to the lives of infants and parents in both the richest and poorest

communities of the modern world by social disadvantage, disease, deprivation, and war and how these destructive effects are motivated by greed, mistrust, and envy and by materialistic detachment, the seductive pressure of technological advances, and religious bigotry. Unfortunately, human collaborative awareness, which grows so impressively in early childhood, is capable of creating a prison of institutions, laws, and beliefs, as well as powerful methods of science that forget how they originated and what motivated their more imaginative beginnings (Whitehead, 1926/1953).

The human sciences, too, will have to learn to adopt a more coherent, multilevel view of human nature by considering the whole child in his or her family. The increasing specialization of those working on the molecular level of vital processes has led to acceptance of a reductive model of developmental causes. However, as the potential mechanisms at a genetic level of analysis are continually being revised and replaced (e.g., Pescucci, Meloni, & Renieri, 2005), we are seeing hypotheses about mechanisms coming full circle to recognize the idea that environmental factors affect the epigenetic regulation of gene expression. This will include factors “ranging from developmental progression and aging to viral infection and diet” (Jaenisch & Bird, 2003, p. 251) and inevitably, as argued here, the effects of the infants' initiatives in interactions with the human world.

Finally, we must recognize the other tendency of both psychological and scientific explanation to gravitate toward complex rational and linguistic models, which are favored by literacy and computational technology. This tendency pulls attention and explanation to the opposite pole of abstraction from the physical-reductive one. The two poles of scientific enterprise leave the middle ground of live, emotionally regulated communication in the dark.

Darwin's Legacy: Curiosity about Origins and Processes of Life Forms and an Integrative Evolutionary Biology, with Implications for Human Nature

Darwin's lasting contribution to the human sciences is a persuasive respect for origins in the prehuman past. He turned ambitious Victorian thinking about the values of human society away from elaborate artificial urgencies of imperial power and rigid adherence to scriptural explanations of human obligations, toward acceptance of forces of vitality that regulate and guide the preverbal habits and emotions of animals and infants in their evolved fitness for an ancient environment. He argued for the power of cre-

ative motives to support life and its survival. In his notebooks he wrote, "Motives are the units of the universe (1998)." He knew nothing of gene molecules or neurons.

In the early part of the twentieth century, natural science, driven by a century of discovery by explorers in every habitat, was animated by a profound curiosity about and admiration for the patterns and functions of life forms and by a comparative approach that attempted to see coherent trends and homologous adaptive structures and strategies for survival across species in the "tree of life."

The first years of the twenty-first century have produced a very different science of nature. We journey in a bewildering sea of facts and correlations—about the molecular intricacies of the genome, about varieties of cell surface architecture and the chemical instabilities of cytoplasm, about the technology of stem cells and manufacturing individuals, about neuron assemblies and the capacity of the brain to process information and to change in plastic ways. Language sciences and artificial intelligence serve a brilliant technology of global electronic communication. There are changes in human industry and mobility: Employment makes mothers and fathers busy out of the home, and a global rapid transport system carries workers and their families out of their historical communities and tempts them to vacations in foreign lands away from inclement weather, where they purchase exotic objects and activities. This exuberance of production and movement can be seen as a wonderful display of human inventiveness and play, but it draws heavily on human energies, creates social divisions, and, in disadvantaged sectors, drives great numbers of children and their parents to a distracted poverty that generates forms of self-abuse and/or antagonism to society.

There are, of course, active forms of understanding in contemporary science that moderate and correct this over-rich, overconfident but narrow vision of reality and sense of mastery over nature, with recognition of regulatory homeotic processes that exercise a directive restraint on acquired diversity of genetic actions among life forms and that favor their cooperation. Among the most important of these are, first, the recognition that *emotions* of animals and humans operate on similar principles to guide social collaboration and development of the young (Panksepp, 2004), and second, a growing acceptance that the *motives* of children assist their own growth of well-being and understanding by attracting affectionate attentions from their parents and by stimulating playfulness and imaginative projects for their vitality in a growing company of peers and adult friends (Trevarthen, 1998b, 2005b, 2005c). The good health and progress of children in any world, and in

any education, depends on this display of natural enthusiasm for social life. It is the principal factor restraining the industrious compulsions of the adult world, with its intricate commercial, legal, and political fabrications. Children's needs bring human motivations back to their origins.

Here are some recent calls by respected scientists for new ideas on how science should seek a balanced view of mental life:

A neuropsychologist, introducing discoveries on the sympathetic brain, writes,

We need a theoretical vocabulary that bridges three domains: our intuitive "folk" conceptions of other people, the explanations offered by social psychology, and the explanations offered by cognitive neuroscience. And we need a method that can extract common patterns across multiple studies, to complement strict hypothesis testing of individual studies. These issues can be addressed, in part, by giving theory and experiment equal time, and by fostering an interdisciplinary approach that includes neuroscience, psychology, philosophy, anthropology and allied disciplines. (Adolphs, 2003, p. 119)

A comparative behavioral scientist who has pioneered affective neuroscience says:

Now that the cognitive revolution is gradually giving way to an emotion revolution, investigators are gradually exhibiting a new taste for the pursuit of what was once deemed scientifically unpursuable—an understanding of what affective processes really are, even in nonhuman animals. . . . Only through the integration of human and animal approaches can deep knowledge in this field be achieved. If we conflate emotions and cognitions too much in our thinking . . . we may retard a fundamental understanding of affective processes and thereby, a real understanding of how cognitive activities are modified by emotional states. (Panksepp, 2003, p. 5)

and

We should be under no illusion that as neuroscientists clarify the *parts* of the brain, they have grasped the *whole*. In general, science is better at dissecting and analyzing the parts of nature than reconstructing them into wholes. Psychology is still the best tool we possess to capture the global capacities of the neuro-mental apparatus. Without psychology we cannot make sense of the dynamic functional organization of the brain. Neuroscientists that do not respect and understand psychology and dynamic principles have little chance of understanding the functional organization of the brain. (Panksepp, 2004, p. 57)

A leader in research on the causes of emotional disorder from the molecular level up expresses his perspective thus:

Genes, early development, adult experiences, lifestyle, and stressful life experiences all contribute to the way the body adapts to a changing environment; and these factors all help

to determine the cost to the body, or “allostatic load.” Studies of these processes involve the disciplines of biology and psychology, but they are incomplete without the input from other fields, such as cultural anthropology, economics, epidemiology, political science, and sociology. These fields provide a description and analysis of the social and cultural institutions and economic forces that affect individual human health. (McEwen, 2001, p. 42)

These opinions clarify the limitations of both rigorously reductive theories constructed to accommodate the data from experimentation and elaborate intellectual models that are detached from spontaneous life activities. Experiments in behavioral science often appear designed primarily not just to test hypotheses, but to generate reports of novelty in professional scientific journals, which apply restrictive standards of presentation and empirical support and require statistical analysis of correlations in measurement. Modeling of cognitive processes in artificial intelligence is driven by mathematical rules to define interactions between factors in systems that have no bodies and that do not move.

In the field of child psychology, such approaches, however well-intentioned, have seemed to confirm that infants need to learn or introject a sense of emotional restraint and to acquire an articulate image or representation of another person and their states of mind to become aware of themselves and their communicative impulses, and that the mother’s role is to supply a sensitively responsive patterning of movements and feelings of moving before the infant can have a self of his or her own. The mechanism of attachment of infant to the mother has been interpreted as one of instinctive appeals for a caregiver’s body contact, support, calming, and nourishment. The psychobiological version of the theory, based on research to test the effects of withholding maternal stimulations on rat pups and nursing monkeys, is articulated in terms of stress reduction and the building up of a physiological system that will serve as an internal regulator and free the young animal of the need to be in such intimate dependence on maternal instincts. In attempts to find an explanation for developmental disorders of the brain that handicap communication as a child grows to adulthood, special importance has been given to verbal analysis of feelings to assist the assumed mastery of interpersonal realities.

In child psychotherapy and psychoanalysis, however, new concepts have grown, informed by infant developmental research, and by psychobiological and neuroscientific advances. These assist the interpretation of severe pathology in children, and how to deal with it (Alvarez, 1992, 1999, 2000; Edwards, 2001; Fonagy, 1998, 2001; Fonagy & Target, 2003; Maiello, 2001; Schore, 2003c). Acceptance

of the interpersonal nature of unconscious and conscious processes has always been at the heart of psychotherapeutic endeavour, now increasingly viewed from an evolutionary perspective integrating attachment theory and neurobiology (Fonagy & Target, 2003; Liotti, 1999; van der Kolk, 1994; van der Kolk, McFarlane, & Weisaeth, 1996). We find a new appraisal of intersubjective “sympathy” in psychoanalytic epistemology. Core affective states, the visceral experiencing of emotions in the therapeutic relationship, are accepted as central to the process of psychotherapeutic change.

The Role of Social Play in Development of Cooperative Awareness

Gradually, in both the human attachment literature and that concerned with maternal care of other young mammals, it has been necessary to admit that inarticulate young have powers to stimulate and guide adult affections and parenting behaviors, and that what infants require is company of a willful, aware, and emotional person who is playfully ready to gently tease, or be teased, and extend a *reaching out for fun* (Reddy, 1991, 2005). But, because the primary motivation for all work on early emotional development and social skills is to find an explanation for emotional and behavioral problems that cause concern through childhood to adolescence, and to investigate effects of insensitive or inconsistent or cruel mothering, there has been a current of theory that discourages attempts to observe healthy and happy behavior in detail. We do not understand well how joy affects the brain and what it contributes to the formation of satisfying and effective child-parent relations, how it fosters further child development, and how it motivates the kind of learning that makes the life of a young person in society full of emotional rewards and achievements and secure and realistic hopes and ambitions, though there have been clear calls for a quest (Emde, 1992; Panksepp & Burgdorf, 2003; Reddy, 2001; Stern, 1990).

We believe that the account of how human capacities for being consciously active and for becoming aware of and expressive to other persons emerge prefunctionally in formation of the bodies and brains of a human embryo and fetus, and the ways brain systems are engaged at all stages in circular regulatory relations by neurohumoral systems with the vital process of the whole body should encourage a greater faith in the powers of the infant to communicate richly. Careful observation of mutually pleasurable engagements has brought remarkable evidence of such an inborn ability. Such observations help explain the conviction of a healthy mother, who has passed through a satisfactory preg-

nancy and been well prepared in her neurohumoral state for love of the baby, that she is greeting a little person. The father, too, indeed all the close family and even indulgent outsiders can share this experience of engagement with a human vitality.

The developments of infancy lead to cooperation in habits and acquired understandings and emotional evaluations. The participation in shared experience is propelled forward by imitative negotiations and trickery in affectionate and carefully moderated conflicts full of enjoyment (Reddy, 2003; Reddy & Morris, 2004; Trevarthen, 2005a). Here the findings of research on animal play are of great interest (G. Bateson, 1955, 1956; Bekoff & Byers, 1998; Panksepp & Burgdorf, 2003). It seems that the joy of exuberant rivalry and immediate imitation of extravagant expressions in moving has benefit for the regulation of the positive use of near-stressful flow in activity, and above all in joint or collaborative activity. At the center of all such celebratory behaviors are rhythmic rituals of action modulated by cycles of energy expenditure and recovery (Turner, 1982). So there is a dance of life joined in every form of collaborative awareness, even one that seems to have a most serious practical purpose.

Prosocial behaviors (Bierhoff, 2002) are not merely democratic but must be guided by sympathies and “moral sentiments” (Smith, 1759/1976), such as are evident in young children. These principles are needed in assessment, therapy, and education of any person of any age who is suffering from the fear, anger, anxiety, and confusion of emotional disorder. Varieties of child emotional disorder can be related to how a child needs to develop, and is equipped by his or her nature to develop, through attachments, friendships, and a lifetime of sociability.

Understanding problems children have when the support from their mother or other caregiver is not normally responsive is, we believe, better served by research on the course of developmental change when a healthy infant is in control of actions and experiences well supported by a sympathetic and happy partner—on what can be missing. The drive to study pathology comes from a reduced or pessimistic perception that the child is a passive vessel, a receiver of developmental training.

Fitting New Brain Science to Human Needs

The final decade of the twentieth century, the “decade of the brain,” brought more detailed, more accurate information about processes in living brains (Cicchetti & Cannon, 1999). New methods of anatomical investigation, of molecular neurobiology and genetics, of functional imaging, and

of standardized interrogation of mental processes by cognitive tests changed the picture. The classical theory had chains of neurons taking in sensory information and processing it into features and object schemes, then activating motor responses and inscribing categories of memory according to rewards and punishments felt in the body. That theory is gone, replaced by one that expects to find widespread patterns of activity originating in regions involved in emotional states and once thought secondary to those presumed to assemble perceptions and memories. The cortex is no longer seen as the supreme integrator of cognitive processes and language, but more like a multifaceted crystallization of impressions illuminated by arousing impulses of subcortical origins: by attentions, intentions, and above all by emotional states that evaluate the risks and benefits of the whole enterprise in subtle, adaptive ways (as emphasized by Damasio, 1994, 1999; Merker, 2005; Panksepp, 1998b, 2000; Tucker, 2001). In short, the brain has become a little more comprehensible as the organ that, with the body, moves a person, one who has a consciousness of the body and the world it is in, a consciousness that serves the skill of movements prospectively and who has emotions and memories that assist in the imagining of the potentialities and values of that future experience.

Resuscitation of interest in the neural correlates of emotional states has led to a new approach to both conscious awareness and memory, both of which had become codified in Byzantine models by one-sided adherence to experimental procedures in which subjects whose freedom of action has been severely constrained make selective responses to express judgments about questions posed by the experimenter in far too limited periods of time (Donald, 2001). The unconscious intentional preparation for rational understanding, and for its articulation in language, has returned to center stage, no longer treated as outside any possible rigorous scientific attention.

Much has been made of the discovery that brain anatomy is plastic to experience (Johnson, 1998), with classical maps of function showing disturbing instability under the influence of practice or the focus of motivation. This switch of interpretation owes much to a straw man built of exaggerations about the claims of anatomists and embryologists regarding the prefunctional mapping of systems in the neural net. But principles of somatotopy mapping between body and brain do apply and are essential to how the brain functions coherently in regulation of the time and space of behavior. Genetic mechanisms do instill adaptive programs of morphogenesis that impose crucial constraints on what the environment can do to change the rules of intelligence.

Moreover, the epigenetic process is regulated to produce age-related transformations in the enterprise of intelligence. A child's mind is not just the consequence of environmental programming and not just a history of emotive events. The abstract mathematics of dynamic systems theory makes cogent criticism of linear causal explanations of motor coordination, conscious conceptions, and memory. But no metaphor of emerging order in patterns of neural energy or their behavioral consequences can explain the initial coherence of an intention, or the emotions that evaluate its prospects. The age-related transitions depend on intrinsic transformations in constraints on brain activity that originate in motive systems that have evolved to regulate a life cycle of changes (Trevvarthen & Aitken, 2003).

All these issues, no matter how much their resurgence in scientific psychology may owe to elaborate methods of brain science or molecular biology of nerve cell differentiation and communication, can be addressed and assessed by accurate investigation of the behaviors of an infant in lively engagement with the world and human society. The integrated purposefulness and awareness of newborns' movements, their emotional expressiveness and their immediate responses to the expressions of another person, and their qualities of contingent response in intimate communication prove that the human brain is designed to do the job of generating and sharing acquired mental states. Infants are born learning; they are profoundly affected in their experience and understanding by the emotions that arise between themselves in their own body and the body and mind of those who take on the responsibility of being caretakers and companions. These adaptations, with their miraculous power to absorb meanings and to create inventions of play in affectionate partnerships, carry destructive energy if the human world gives no support or imposes unsupportable stresses.

Scientific Guidelines for Care of Stressed Young Children and Their Families

Effective child psychopathology has to be multilevel and transdisciplinary (Cicchetti & Dawson, 2002; Cicchetti & Rogosch, 1996). A *whole person psychology* is needed to begin a useful science of infant mental states and to understand how stresses in relationships may predispose a child to fear and anger that will color relationships in later years. Knowing that the hippocampus or orbitofrontal cortex of the right hemisphere grows throughout life and can be stunted or deformed by emotional stresses can help focus our awareness and sympathy for the young child's plight, but it cannot replace the need for sensitive awareness of the

face, voice, and expressive gestures of the real individual child that the parents and persons offering clinical or social support have to respond to and guide. It is important that infants are born genetically different in complex ways that give them different initial strengths and fragilities, but this much should be obvious to any sensitive parent or therapist. The genes that correlate with a child's behaviors, or behaviors of family members, can give only very approximate evidence of what that child's motives are and how they will change.

Care for children at risk of pathology in consequence of neglect or abuse cannot be effective if it bypasses the intrinsic capacities of the child for sympathetic engagement with other persons' actions and feelings and for playful experimentation with the joys and risks of shared activity. Decades of experience in the recovery of happy lives from circumstances where infants have been deprived of proper human care supports the message of Bowlby's attachment theory, which has had a profound effect on medical and educational care of troubled children and on parental awareness of children's needs (Greenspan, 1981). However, Bowlby (1958) imagined the child as acquiring a cognitive internal working model of what Winnicott (1960) called a "good enough" mother. We know now, through research on the intricate signals of touch, vocalization, and eye contact in mother-infant protoconversations and games, that the infant's motives for relationships go beyond those that attract and sustain mothering (Beebe et al., 1985; Stern, 1974, 2000; Trevvarthen, 1979; Tronick et al., 1978).

The lively intersubjective imagination of a child needs to participate in a generous play with meanings to make sense of the cultural world, with all its arbitrary understandings of reality. The infant is seeking to interact with intentions and interests from early weeks (Trevvarthen & Aitken, 2001). The motives for this play are dynamic and rooted in the rhythmic impulses and expressive gestures of unconscious human volition. Therapy must base its effort at this level, sensitive to those rhythms and expressions (Caldwell, 2005; Nafstad & Rodbroe, 1999; Schore, 2003b).

The efficacy of improvised music therapy for achieving sympathetic communication with emotionally disturbed or mentally handicapped human beings of any age both depends on and proves this intrinsic "communicative musicality" (Bunt, 1994; Elefant, 2001; Gold, Vorachek, & Wigram, 2004; Malloch, 1999; Merker & Wallin, 2001; Nordoff & Robbins, in press; Pavlicevic, 1997; Trevvarthen & Malloch, 2000, 2002; Wigram, 2004). With people whose sense of self is fragile, where meaning is lost or not easily found, music has unique powers which the resourceful music therapist can use to support integrative and self-

restorative processes (Montello, 1999; Robarts, 2003, in press). We have little knowledge of how the brain mediates engagement with musicality of human expressive body movement (Panksepp & Bernatzky, 2002), but the power of this level of intersubjectivity, one that corresponds with the natural engagements of vocal and gestural play and touching with infants, is confirmed (Burford & Trevarthen, 1997).

Attachment-Based Therapy for Neglected or Abused Children and Parents Who Foster or Adopt Them

The experience of those who offer support for disturbed children and their families, and in particular those rebellious or resistant children who have been removed from their biological parents for their own protection, is that it is necessary to get into immediate responsive engagement with the child by the same kind of intuitive forms of communication as are used by affectionate and happy parents with infants and toddlers everywhere (Archer & Burnell, 2003; Hughes, 1997, 1998). In this communication, sympathy for what the child is feeling, genuine emotional response that is accepting and flexible, and good humor in play are as essential as calm attentiveness in listening to the child, and firmness in setting clear boundaries, both physical and emotional. A scientific or clinical detachment is to be avoided. For the severely abused child the recovery of joy in play requires a longer, more complex therapeutic treatment; PTSD associated with trauma distorts normal patterns of interpersonal engagement, triggering an overload of confusing sensations that frequently lead to dissociative or out of control reactions, so that the sensory and dynamic experiences of play have to be treated with clinical perception, understanding and skill (Robarts, in press; Rogers, 1995; Schore, 2001b, 2003c; Siegel, 2003; Sutton, 2002; van der Kolk et al., 1996).

Play means interaction with any impulses for adventurous and enjoyable movement and experience. It means sharing expressions of joy and surprise (Panksepp & Burgdorf, 2003). It taps a basic emotion in social sharing, one that is close to and supportive of the basic emotions for pleasure in attachment. As the ethologists have discovered by studying the instinctive movements of young animals' chasing and pretend fighting, play is affiliative (Bekoff & Byers, 1998). It strengthens and develops social bonds while sorting out social hierarchies. Play therapy draws on these psychobiological principles in a systematic way (Jernberg & Booth, 2001). For a troubled child, making happy and trusting friendships in playful and intimately affectionate responsive ways is a key to positive learning and emotional security.

Video-recorded evidence of the emotional nature and patterning of this kind of communication is beneficial not only for therapists and teachers, but also for parents attempting to guide a child to better emotional health (Beebe, 2003; Forsyth, Kennedy, & Simpson, 1995; Gutstein & Sheely, 2002; Jansen & Wels, 1998; Juffer, Bakermans-Kranenburg, & van Ijzendoorn, 2005; Schechter, 2004). This is how video feedback is employed as a detailed record of interacting behaviors and a prompt for more supportive and constructive communication.

Spontaneous and creative art therapies in dramatic acting, dance, or music all engage with the timing and expressiveness of direct intuitive communication in the present. They engage the aesthetic dynamic forms of non-verbal and verbal in expressions that are the basis of creative-constructive therapeutic change (Gilroy & Lee, 1995; Levine, Knill, & Levine, 2003; Robarts, 2003, in press). The play of communication is creative by means of an interpersonal improvisation in which partners are at the same time free to be expressive in themselves and instantly reactive to what others do, and therefore open to guidance and learning. Real intuitive engagement is necessary for the emotions between them to flourish, as with infants (Reddy & Trevarthen, 2004).

Specific memories and verbal explanations guide awareness and direct interests. In normal life, these cognitive components, built up through experiences in established relationships, strengthen the prospective control of attentions and intentions and lead to more knowledgeable and skillful action. In psychopathology, the cognitive contents of memory intrude in imagination and carry affective material that blocks effective consciousness and action. Therapy for adults requires work with these contents. At the same time, engaging with the emotions and a clear focus on the interpersonal motives that direct movements in the present can regulate disturbing or inhibiting material from memory and imagination, finding a path to more rewarding and creative purposes in relationships that are affectionate and trusting (Kerr, 2005; Kohut, 1984). A therapist aiming to help a child with developmental psychopathology by intersubjective or interpersonal means has responsibility to stay with the child through periods of resistance or rejection to find this path (Archer & Burnell, 2003).

ACKNOWLEDGMENTS

We would like to thank Dr. Jacqueline Robarts of the Nordoff Robbins Music Therapy Centre, London for her expert advice on therapy for traumatized children.

SUMMARY AND FUTURE DIRECTIONS 177

REFERENCES 180

Neuroimaging technology has provided the means to non-invasively visualize the normal and abnormal development of the brain. This has allowed the linking of biological information such as genotypes or postmortem data with behavior through in vivo images of brain structure and function, providing a crucial bridge between developmental psychology and the broader discipline of developmental biology. The ability to correlate psychiatric illnesses with measurable brain changes has made them physically tangible in a way that has helped people to see them as biological illnesses and has been an important factor in the de-stigmatization of individuals with mental disorders and their families. On a societal level, data from neuroimaging studies of normal development in adolescence have entered social and political discourse in issues ranging from the legal age at which a teenager should drive to whether juveniles should be given the death penalty.

The excitement at being able to see this reclusive organ, so central to our personal and social selves and yet so long hidden behind its protective casing of bone, has led to a still accelerating explosion of studies using neuroimaging techniques. The purpose of this chapter is to provide a snapshot of results of those studies that provide information about the maturation of brain anatomy. As studies of normal and abnormal brain development are mutually in-

formative, we begin with discussion of studies of normal brain development and then proceed to findings associated with psychopathology.

The vast range of disorders that affect brain and behavior renders a comprehensive account beyond the scope of this chapter. Although broadly speaking the developmental trajectory of the brain extends from conception until death, we have chosen to consider as neurodevelopmental disorders those which manifest on the path toward adulthood and to somewhat arbitrarily exclude disorders normally occurring during senescence. We are also constraining our review to studies of children and adolescents. Rather than attempt an encyclopedic coverage of brain disorders, we have included reviews of literature of two general groups: those relatively common psychiatric conditions that have accrued a significant body of structural neuroimaging literature, and selected neuropsychiatric disorders with known genetic abnormalities that are illustrative of the interaction between developmental anatomy and psychopathology. Lack of attention to a particular disorder should not be interpreted as a comment about relevance of that disorder clinically.

This chapter is divided into four sections: methodological issues, typical pediatric brain development, examples of atypical brain development, and a discussion of the

present and future role of structural neuroimaging in the study of neurodevelopment.

METHODOLOGY

Attention to methodological issues is crucial for interpreting results of neuroimaging studies. While the same can be said for any research tool, the ease with which neuroimaging allows one to just “look” at pictures of the brain can obscure the multitude of complex technical and statistical processes that are involved in producing imaging data. Imaging hardware and analytic techniques have been improving at a rapid rate, making comparisons between results of studies performed at different times in the development of the field a matter for caution.

Study designs have also been changing based on findings from the first generations of neuroimaging experiments. This has been particularly important in studies of neurodevelopment in children, where it was not known until the first such studies became available how much variability there is between individuals, between genders, and over the course of development.

In this section we begin with a brief history of neuroimaging techniques to provide background for a discussion of the major structural imaging modalities currently in use. We then discuss issues related to image analysis methods and study design. The goal for such a short summary of this large and dynamic field is primarily to give a sense of issues to take into consideration when evaluating neuroimaging studies.

Evolution of Neuroimaging Techniques

Imaging of the central nervous system (CNS) began with radiographs in the early 1900s, shortly after the discovery of X-rays by Roentgen in 1895 (Leeds & Kieffer, 2000). The first techniques to improve visualization of CNS structures were ventriculography, devised in 1918, which consisted of the injection of air into the ventricles; and pneumoencephalography, a variant in which air was instead injected into the spinal canal through a lumbar puncture. Both of these techniques used the low electron density of air as a type of contrast (Lewis, 1996). The presence of air made the shapes of the ventricles visible, and thus indirectly could provide information about associated CNS structures, for example, if the ventricular shape had been distorted by some CNS abnormality. Cerebral angiography provided a similar type of indirect information but in this case through visualization of the vascular system. It was

introduced by Egas Moniz in 1927, when he opacified the carotid artery through introduction of a sodium iodide solution. Substantial refinements in cerebral angiography through the 1960s eventually decreased the need for ventriculography and pneumoencephalography, but like them, it was an invasive technique only undertaken in the presence of clear clinical need.

The clinical introduction in 1971 of computed tomography (CT), originally called computerized axial tomography or CAT scanning, revolutionized the study of the CNS by allowing direct and noninvasive visualization of brain structures. It was also a radiographic technique based upon the interaction of different tissue types with X-rays, but combined multiple views using a mobile X-ray source and newly developed fast computers to create images of soft tissues like the brain. The success of CT led to intense interest during the 1970s in combining computational techniques with a variety of different physical properties for diagnostic and imaging purposes. Many of the techniques in use today originated then, including magnetic resonance imaging (MRI), magnetoencephalography (MEG), optical imaging, positron emission tomography (PET), and ultrasound.

Nuclear magnetic resonance, the basic physical principle underlying MRI, was first described during the 1940s. Felix Bloch and Edward Purcell were awarded the Nobel Prize for this achievement in 1952. They independently discovered that if a sample material is placed in a strong magnetic field and exposed to radiofrequency (RF) energy of a certain frequency, a detectable signal (or “magnetic resonance”) is generated based on the interaction of the sample and the field. The potential for medical applications became apparent in the 1970s, with Raymond Damadian’s discovery in 1971 that different tissues could have different magnetic resonance properties (Damadian, 1971), and Paul Lauterbur’s demonstration in 1973 of a technique using magnetic field gradients to localize the source of magnetic resonance signals (Lauterbur, 1973).

The combination of these advances allowed the creation of images of tissue structure through a process in which the signal associated with a specific volume of tissue, called a *voxel*, is represented with a digital image pixel. The pixel intensity varies according to the magnetic resonance properties of the tissue, so that when the pixels are placed in their proper anatomic location an image is formed reflecting the magnetic resonance properties of the sample tissues. This is particularly useful in the brain because of the differing magnetic resonance properties of major brain components such as neurons, myelin, and cerebrospinal fluid (CSF). The ability to create highly detailed anatomic

cal maps of brain structures resulted in MRI becoming a major imaging modality for study of the central nervous system by the 1990s.

The capabilities of MR technology have continued to rapidly improve. Image resolution is now routinely in the 1 mm to 2 mm range, within the range necessary for description of the often subtle changes associated with neurodevelopmental disorders. Some research applications are able to visualize structures down to the level of individual cortical layers, allowing the linking of data from imaging and histological studies. In addition, MRI has been particularly important in the study of neurodevelopment because it does not involve exposure to ionizing radiation. Therefore, it has become accepted as safe for use in children, including healthy children, and for multiple scans during longitudinal studies.

Parameters to Consider in Structural Pediatric Neuroimaging Studies

In the pediatric anatomic neuroimaging literature, inconsistent or contradictory findings seem to be more the rule than the exception. Differences in (1) image acquisition, (2) image analysis, (3) patient and control populations, and (4) cross-sectional versus longitudinal study design may all contribute to these discrepant findings. Parameters to consider in each of these domains are discussed next.

Image Acquisition

Major technical objectives in imaging studies of brain structure include establishing contrast between different tissue types, obtaining a sufficient degree of resolution for visualization of structure details, and minimizing exam length. MR exams are based on the principle that some types of molecules in the human body have a very slight natural magnetization. The one most frequently examined in MRI is the water molecule because it is present in the body in such high concentrations. Protons in the weakly magnetic water molecules tend to line up with the strong magnetic field of the MR scanner. A brief RF pulse temporarily disturbs this alignment, followed by a gradual return to the baseline state, a phenomenon called “relaxation.” There are two different types of relaxation based on different physical properties of the tissue: spin-lattice or T1 relaxation and spin-spin or T2 relaxation. Proton density (PD) is a description of how many hydrogen atoms are in the sample. Each of these properties affects the way a tissue will look on an MR image. In an MRI session, the sequences of energy pulses (the aforementioned RF pulses

and the changing magnetic gradients used for localization) are precisely timed to highlight specific features of a tissue based on T1, T2, and PD properties.

For studies of brain structure, the MRI sequence is typically designed to maximize the amount of contrast between gray matter, white matter, and CSF, as such contrasts define the boundaries of most brain structures. Images that emphasize the T1-related differences between tissues (“T1-weighted”) are good at highlighting contrast between gray and white matter, while PD weighted images are better at separating gray matter and CSF, and T2 weighted images are best for seeing most types of pathology. The most common single modality used in for studies of brain neurodevelopment is the T1 weighted. However, many studies obtain a combination of T1, T2, and/or PD weighted sequences in the same session and then average them together. The advantage of this type of acquisition is that by combining information from the image sets, automated computer programs can better discriminate gray matter, white matter, and CSF (Rajapakse et al., 1996); the disadvantage is the added length of the MRI exam.

Image resolution is determined by the size of the voxels provided by a particular imaging sequence. Voxels are usually grouped into two-dimensional slices, which then are stacked to contain the data from the whole brain. The size of the voxels and thickness of the slices is especially critical for small but clinically pertinent subcortical structures. *Partial voluming* is a term for a voxel that contains two different tissue types, and so cannot be accurately assigned to either, blurring the border of small structures. Generally, resolution is purchased with the currency of time: improvements in image quality must be weighed against patient discomfort from prolonged time in the scanner.

Most of the studies reviewed in this chapter concern data obtained from T1- or T2-weighted images, which are what people are usually referring to when they say “MRI.” However, MR parameters can be altered to examine other tissue characteristics. MR techniques with significant applications to complement studies of the development of brain structure include T1 and T2 relaxometry, magnetization transfer imaging (MTI), and diffusion tensor imaging (DTI).

T1 and T2 Relaxometry and Magnetization Transfer Imaging

While T1 and T2 properties of tissues can be used to generate contrast for anatomical studies, it is also possible to directly quantify how the relaxation properties of a tissue may vary by tissue type, region, developmental stage, or in the presence of pathology. Magnetization transfer imaging

(MTI) is a relative of relaxometry that has been gaining increased attention in recent years due to its ability to measure changes in WM primarily related to the status of myelination. MTI measures the impact of protons bound to macromolecules on MR-visible free water protons (Wolff & Balaban, 1989). In WM, the macromolecular pool is located primarily in myelin. As myelination occurs, it increases the concentration of tightly bound protons in tissue, which can affect signal intensity in the less tightly bound protons visualized by MR (Barkovich, 2000). The extent of this effect can be calculated on a voxel-by-voxel basis, most frequently expressed as the ratio of signal intensity obtained from standard sequences and sequences designed to saturate the bound proton pool, the magnetization transfer ratio (MTR; Wolff & Balaban, 1994).

Diffusion Tensor Imaging

DTI is a technique based on the principle of anisotropic diffusion, the tendency of water to diffuse in a particular direction based upon local structural constraints (Taylor, Hsu, Krishnan, & MacFall, 2004). Anisotropy measures are typically higher (i.e., show more directionality) in white matter than in gray matter because of directed motion of water molecules along white matter fiber tracts; anisotropy values also tend to increase in tissues as myelin increases, as during maturation (Neil, Miller, Mukherjee, & Huppi, 2002). DTI tractography provides a method for describing coherent structures, such as WM tracts, that may be informative regarding changes in connected structures (Taylor, Hsu, et al., 2004). For example, with DTI, it may be possible to determine whether a given area of cortical thinning is a local finding, is associated with a disruption in the thalamocortical tract projecting to it, or with an abnormality in the pertinent thalamic nuclei (Behrens et al., 2003).

Image Analysis

Validation of MR image analysis techniques is hindered by lack of an absolute gold standard. Postmortem data are less than ideal on several counts. When removed from the intracranial cavity and the CSF in which it is immersed, the brain collapses on its own weight, distorting in vivo morphology. Fixation and drying processes affect different brain structures to different degrees, with gray matter and white matter shrinking at separate rates. Age itself is a confound, as younger brains have higher water content and are differentially affected by fixation processes.

Studies using artificial brain models that mimic the shape and tissue characteristics of the human brain can be

useful, but valid models are difficult to construct. The standard for validation of automated measures for the quantification of many structures remains a comparison to results obtained from manual tracing by expert human raters.

MR image data pixels may have only one intensity value. At the time of image acquisition, these values may range from 1 to 65,536 (2^{16}). However, to reduce the memory requirements for computation, most image analysis systems restrict this intensity value range to 256 (2^8). A general goal of structural image analysis is to classify each voxel in the image data set according to tissue characteristic (e.g., gray matter, white matter, CSF, vasculature), as well as to assign it to the structure or region in which it belongs.

Classification of tissue into different types is usually accomplished by computer algorithms that create an intensity histogram of all of the voxels in the image and then fit Gaussian functions to the distribution to infer the probabilities of a given intensity corresponding to a given type of tissue. This information is sometimes supplemented with probabilistic atlases to help determine whether a given voxel is gray matter, white matter, or CSF based on its location in the brain (Collins, Holmes, Peters, & Evans, 1995).

Once the voxels have been classified, the number of voxels in a given region may be counted to provide volume estimates of gray matter, white matter, and CSF. Lobar volumes are most commonly reported, but as greater anatomical specification is achieved smaller and smaller subregions can be accurately quantified (see Figure 3.1).

Another approach to comparing brain anatomy from MR images is to create “average” brains for each group that lend themselves to statistical analysis. The challenge to this approach is to register or align the different brains in a standardized way so that a voxel from one brain image will correspond meaningfully to a voxel from another brain image. High individual variation in cortical sulcal and gyral folding patterns makes this one-to-one correspondence difficult, although techniques to anchor the average shapes by aligning certain less variant sulci have greatly advanced the utility of this approach (see Figure 3.2; Thompson et al., 2004).

Selection of Patient Populations

A challenge shared by both genetic and imaging studies is that current psychiatric diagnostic criteria are largely descriptive. This reflects the current gaps in our knowledge about the biological mechanisms associated with observed clinical phenomena and the thus modest applicability of such knowledge to guiding treatment decisions. As greater understanding of mechanisms emerges, it is likely that di-

Figure 3.1 The typical sequence of processing MRI data: (a) obtain T1- and T2-weighted images, (b) segmentation procedure, and (c) parcellation of brain into subdivisions for regional quantification of tissue volumes.

agnostic schemata will change; but for now *Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV)* criteria are poorly suited to categorize homogeneous genetic or neuroanatomical subtypes.

Even when using a standard diagnostic system like the *DSM*, studies vary considerably on inclusion and exclusion criteria, most notably as to how to address the issue of comorbidity. Some studies will attempt to exclude subjects with any comorbidity, other will include these subjects with descriptions of existing comorbidities, and some ignore the issue altogether. The effects of these decisions on imaging study outcomes are difficult to predict. Other parameters thought to affect brain morphometry that often differ between studies are handedness (Geschwind, 1978; Kertesz, Polk, Black, & Howell, 1992; Witelson, 1989) and intelligence (Andreasen et al., 1993; Reiss, Abrams, Singer, Ross, & Denckla, 1996; Willerman, Schultz, Rutledge, & Bigler, 1991). Education and socioeconomic status have been reported to influence brain size as well, although the interdependence with factors such as nutrition, prenatal care, and IQ is not clear.

Figure 3.2 Sulcal alignment: After careful separation of brain from nonbrain voxels, 38 sulcal curves on each subject's cortical surface are manually defined. The sulcal demarcations are used as anchors to create a deformation map, which warps the anatomy of one image onto another while matching sulcal demarcations.

Selection of Control Populations

The first neuroimaging studies performed in children typically drew their normative data from children referred for clinical reasons whose scans were subsequently read as normal. This approach is problematic on multiple counts. It has become increasingly appreciated that the type of findings typical of neurodevelopmental disorders may not be visible to even a trained radiologist, but nevertheless still have the potential to impact quantitative research measures such as cortical thickness. Some clinical diagnoses such as Attention-Deficit/Hyperactivity Disorder (ADHD) may be overrepresented in children referred for clinical scans. In addition, a small but perhaps meaningful number of healthy children may have scans read as abnormal, such that excluding these subjects confounds comparisons to clinical groups. Recruitment of healthy subjects directly from the community provides a more appropriate sampling technique for assessing normal development, although this in turn demands consideration of questions about whether a given study design is better served by a control population that matches population norms versus one that is as homogeneous as possible.

Cross-Sectional versus Longitudinal Study Design

The enormous normal variability in size of brain structures calls for large samples and longitudinal study designs to characterize the heterochronous developmental changes of the pediatric population. Conclusions about developmental trajectories drawn from cross-sectional data can easily be in error due to inherent statistical issues. However, multiple challenges exist in carrying out longitudinal imaging studies. Retaining subjects over the course of a study that may last decades is a task difficult to accomplish without a highly trained and stable research team. On a technical

side, MRI images can be highly sensitive to differences in MR scanner hardware, and the potential for changes in hardware during the course of a lengthy longitudinal study thus can potentially affect results. Assessing the ability to maintain consistency in measurement is an essential portion of longitudinal studies. For example, in a study conducted at the NIMH, the feasibility of longitudinal studies was supported by the relative consistency of morphologic measures from scans acquired at 2- to 4-week intervals (Giedd et al., 1995). This indicated that, given a stable MRI scanning platform, quantitative differences in longitudinal scans would be reflections of genuine changes in brain structure and not from variability related to the scan acquisition itself.

TYPICAL DEVELOPMENT

Surprisingly little has been known until recently about the development of the brain in healthy children and adolescents. Postmortem data are rare and prone to sample bias due to the low mortality rate and small number of autopsies done in this age range. For example, the Yakovlev collection of roughly 500 normal brains contains only about a dozen between the ages of 4 and 18 (Haleem, 1990). This section begins with a brief review of the major steps of brain development, followed by a summary of findings from neuroimaging studies.

Key Steps in Early Brain Development

Information from postmortem studies has shown the progression of brain development through a series of critical steps (see Figure 3.3). *Primary neurulation* refers to the development of the neural tube, which is the source of future CNS development and is usually complete by 3 to 4 weeks of gestation. Abnormalities in neural tube formation result in birth defects such as spina bifida and meningomyelocele (Victor, Ropper, & Adams, 2001). Development of key forebrain and facial structures, called *prosencephalic development*, occurs during the remainder of the first trimester. The next stage is *proliferation*, which occurs for neurons primarily in the 3rd and 4th months of gestation, and for glia extends through the 1st year of life (Rakic, 1988). *Migration* occurs during the 3rd to 5th months, in which proliferating neurons migrate from their origins near the ventricles to destinations in the cortex, moving along a scaffolding of glial cells (Rakic, 1990).

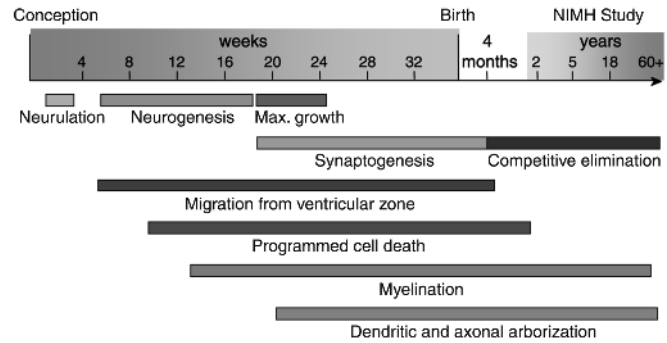

Figure 3.3 Sequence of events in brain maturation.

After migration, a period of rapid cell death called *apoptosis* occurs, resulting in the removal of approximately 50% of neurons between 6 months gestation to 1 month after birth (see Figure 3.3).

The remaining processes of brain development include proliferation and organization of synapses and the myelination of axons. Both of these begin before birth and extend well into postnatal life. The brain continues to grow rapidly in the first 2 years of life, by which time it has achieved 80% of its adult weight. Increases in size continue more slowly thereafter, with 90% of brain weight achieved by age 5 (Dekaban & Sadowsky, 1978) and a largely adult appearance of the brain by age 10 (Jernigan, Trauner, Hesselink, & Tallal, 1991). Huttenlocher (1979) found that the density of synaptic connections increases rapidly after birth, by 2 years of age reaching a level approximately 50% greater than that typically seen in adults. This is followed by a period of loss of synaptic connections called pruning. This pattern appears to occur in a similar fashion but at different rates in different brain regions. For example, the period of maximum synaptic density occurs in the visual cortex by approximately 6 months postnatally and decreases by about 50% between ages 1 and 5 years; while in the prefrontal cortex, it does not reach maximum synaptic density until approximately 24 to 36 months and does not begin to decrease until age 7 (Huttenlocher & Dabholkar, 1997).

Myelination also occurs regionally in an orderly process that begins in the brain stem at 29 weeks (Inder & Huppi, 2000). In general, myelination appears to proceed from inferior to superior and posterior to anterior. Volpe (2000) has summarized more specific principles regarding which pathways tend to be myelinated first: proximal pathways before distal, sensory pathways before motor pathways, projection before association pathways, and from the central loci toward the frontal and occipital poles, with the occipital poles maturing first. The period of time between the

first appearance of myelin in a region and its reaching its mature form varies, ranging from 6 weeks in the posterior limb of the interior capsule to 69 weeks in portions of the frontal lobe (Kinney, Brody, Kloman, & Gilles, 1988). Benes (1989) compared myelination in a region along the surface of the hippocampus between children 0 to 9 years old and 10 to 19 and found a 92% increase after correction for increases in total brain volume. Although the most prolific period of myelination occurs in the 1st year of postnatal life, maturation continues for a prolonged period. Postmortem data has found changes in myelin to continue at least into the 2nd decade of life (Benes, 1989; Yakovlev & Lecours, 1967), and as discussed in the neuroimaging section below white matter volumes increase until the 4th decade (Bartzokis, 2004).

Neuroimaging Studies of Normal Brain Development

The emergence of noninvasive neuroimaging techniques, particularly MRI, revolutionized the ability to study brain development. For the first time structural changes could be mapped in healthy children and related to other aspects of development such as cognitive and emotional function. Neuroimaging has also made possible studies of large enough samples of healthy children to appreciate the enormous degree of variability present within a typically developing population. One of the more unexpected findings was the complexity and duration of postnatal brain development, with regionally specific patterns of increase and decrease occurring well into late adolescence and adulthood (Bartzokis et al., 2001; Giedd, Blumenthal, et al., 1999). Another important contribution of neuroimaging has been to make feasible longitudinal studies of brain maturation and thus begin to discern the trajectories associated with normal and abnormal development. In this section we review some of the major findings that have arisen from neuroimaging studies, with an emphasis on data obtained from our group's ongoing large-scale longitudinal studies at the National Institutes of Mental Health.

Fetal and Perinatal Brain Development

The earliest neuroimaging studies of brain development using CT in the 1970s and MRI in the 1980s focused on qualitative descriptions of gray and white matter during the first 2 years of life (Barkovich, Kjos, Jackson, & Norman, 1988; Holland, Haas, Norman, Brant-Zawadzki, & Newton, 1986; M. A. Johnson & Bydder, 1983; Levene

et al., 1982; McArdle et al., 1987). A stable developmental sequence of brain images in T1 and T2 weighted MR studies has been described. The infantile stage (less than 6 months) is characterized by a contrast pattern opposite to what is seen in adults; in T1 images of infants the cortex is lighter than the underlying axonal regions, whereas in adults the cortex is darker. The adult pattern emerges around 12 months of age, after an intervening crossover period during which gray and white matter are not well differentiated. Similar maturational-related changes in contrast are seen on T2-weighted images but slightly later. MR studies quantifying T1 and T2 relaxation times found that both significantly shortened during over the first 2 years, consistent with a substantial loss of water content in both gray and white matter in addition to arrival of macromolecular precursors to myelination and finally myelination itself (Inder & Huppi, 2000; Paus et al., 2001). As may be expected, the crossover occurs at different times in different regions of the brain, as different regions myelinate at different rates.

MRI studies performed prior to birth or of infants born prematurely have made possible the *in vivo* description of brain structural development from early in pregnancy (Girard, Raybaud, & Poncet, 1995; Rivkin et al., 2000). Although concerns about potential risks to the developing infant limit fetal MRI use, especially during the first trimester, no significant evidence of adverse effects has been found, increasing the likelihood that this will become a more common procedure. In addition, current interest in mapping developmental abnormalities as early in their trajectory as possible, and in delineating the role of adverse birth events in later outcome, is increasing attention to the value of obtaining prenatal brain measurements.

Huppi et al. (Huppi, Warfield, et al., 1998) applied automated methods to the quantification of gray matter, unmyelinated white matter, myelinated white matter, and CSF in preterm and full-term infants from 29 to 41 weeks gestational age. They found an increase in brain tissue volume of 22 ml/week and a fourfold linear increase of primarily cortical gray matter. The volume of myelinated white matter increased markedly between 35 weeks and term, and CSF did not show significant changes.

Myelination and gyrification are both aspects of brain development that are not easily ascertainable with ultrasonography. Interest in gyrification in particular has arisen from its applicability as an index of gestational maturation. Fetal MRI studies have described fetal brain maturation from as early as 13 weeks of gestation, including formation of the primary sulci and insula by 15 weeks. The major

sulci, except for the occipital lobe, are in place by 28 weeks of gestation, after which secondary and tertiary sulci are elaborated, with nearly all gyri present by birth. The patterns of the sulci and gyri continue to increase in complexity after birth, likely related to changes in cell-packing density and maturation of subcortical tracts (Garel, Chantrel, Elmaleh, Brisse, & Sebag, 2003).

Imaging Studies in Older Children and Adolescents

Detailed structural neuroimaging studies of older children began to be reported in the 1990s. The first studies of healthy development were cross-sectional and often consisted of MRI scans collected in children being scanned as part of evaluation for a clinical complaint and whose scans were subsequently read as normal. Nonetheless, it became apparent that although overall brain volume was not changing significantly, significant remodeling appeared to be occurring, as reflected in changes in relative volumes of gray matter, white matter, and CSF (see Figure 3.4; Jernigan & Tallal, 1990; Reiss et al., 1996; Schaefer et al., 1990).

In 1989, the Child Psychiatry Branch at the National Institute of Mental Health (NIMH) initiated a large longitudinal study of normal and abnormal brain development, which is still ongoing. The study was designed to assess the hypotheses that many of the most severe neuropsychiatric disorders of childhood-onset are associated with deviations from normal brain development and that the anatomical substrates of this may be detectable by MRI. The study includes twin and nontwin healthy controls and subjects from a variety of diagnostic groups. Participants are scanned at approximate 2-year intervals, and many have been scanned three or more times, allowing the as-

Figure 3.5 NIMH normal development study recruitment.

essment of individual trajectories without the limitations of attempting to use cross-sectional data to address longitudinal questions (Kraemer, Yesavage, Taylor, & Kupfer, 2000). As of August 2005 the data set included approximately 3,800 scans from 1,850 subjects, about half classified as having normal development and half from various diagnostic groups, such as ADHD and childhood-onset schizophrenia (COS).

Concerns regarding potential confounds from using controls that had been referred for clinical purposes led to the adoption of a stringent screening process. The healthy control subjects are recruited from the community and undergo physical and neurological examinations, clinical interviews, family history assessment, and an extensive neuropsychological battery (see Figure 3.5).

Each child undergoes an MRI exam including a T1 weighted sequence for anatomical analysis. Once the images are acquired, they are analyzed by a variety of automated and manual techniques through collaboration with several imaging centers throughout the world. Further details of the testing and screening of this sample and the methods of image analysis are published elsewhere (Chung et al., 2001; Giedd, Blumenthal, et al., 1999; Giedd, Snell, et al., 1996; Zijdenbos, Dawant, & Margolin, 1994). In the remainder of this section, we focus on results obtained from this study.

Total Cerebral Volume

Total cerebral volume was found to increase and then decrease between ages 4 and 20 years (see Figure 3.2;

Giedd, Blumenthal, et al., 1999), a phenomenon not previously seen with postmortem data (Dekaban, 1977; Dekaban & Sadowsky, 1978) or previous cross-sectional imaging studies (Giedd, Snell, et al., 1996; Jernigan & Tallal, 1990). Although head circumference increases from age 4 to 18 years (approximately, 2.0 inches in boys and 1.9 inches in girls; Nellhaus, 1968), this is accounted for by an increase in thickness of the skull and soft tissues (Shapiro & Janzen, 1960) and, to a lesser degree, by an increase in ventricular volume (Jernigan & Tallal, 1990). Male brains were found to be approximately 9% larger on average than those of females. This difference was statistically significant even when controlling for height and weight. A similar finding of brains being 10% larger in boys was reported by a different group in a cross-sectional study of 85 normal children (Reiss et al., 1996).

Ventricles

In this sample, lateral ventricular volume increased robustly with age, a fact not widely appreciated for children and adolescents. Enlarged lateral ventricles in adults compared with children was also reported by Jernigan and Tallal (1990). This pattern is noteworthy in light of the fact that increased ventricular volumes, or ventricular-to-brain ratios, are associated in a nonspecific fashion with a broad range of neuropsychiatric conditions. That this phenomenon is a normally occurring event in healthy adolescents adds to the complexity of interpreting changes in ventricular volume in patient populations.

Cortical Gray Matter

Cortical gray matter volume tends to follow an inverted U developmental course, with volumes peaking at different times in different lobes (see Figure 3.6). Volume also appears to differ by sex. For example, frontal lobe gray matter reaches its maximal thickness at 11.0 years in girls and 12.1 years in boys. Temporal lobe cortical gray matter peaks at 16.7 years in girls and 16.2 years in boys. Parietal lobe cortical gray matter peaks at 10.2 years in girls and 11.8 years in boys (Giedd, Blumenthal, et al., 1999). As gray matter volume reaches its maximum at about the time of puberty, a reduction in cortical gray matter volume is interpreted as maturation, in the sense that it is becoming closer to the adult state.

To examine cortical gray matter development with greater regional specificity, we examined the change in gray matter density on a voxel-by-voxel basis in a group of 13 subjects who had each been scanned four times at approximately 2-year intervals (Gogtay, Giedd, et al., 2004).

Cortical landmarks were manually selected and used as anchors to ensure accurate matching of regions between individuals. An online animation of these changes is available as supporting material on the Proceedings of the National Academy of Sciences web site (<http://www.pnas.org/cgi/content/full/0402680101>).

The voxel-based measures confirmed the nonlinear and heterochronic nature of gray matter maturation seen in the earlier report based on lobar measures. Prepubertal gray matter increase is followed by loss beginning at different ages in different regions. Cortical gray matter loss occurs earliest in the primary sensorimotor areas and latest in the dorsolateral prefrontal cortex and superior temporal gyrus. The general pattern is for those regions subserving primary functions, such as motor and sensory systems, to mature earliest, and the higher-order association areas that integrate those primary functions to mature later. For instance, in the temporal lobes, the latest part to mature is the superior temporal gyrus and sulcus, which serves as a heteromodal association site integrating memory, audiovisual input, and object recognition functions, along with prefrontal and inferior parietal cortices (Calvert, 2001; Martin & Chao, 2001; Mesulam, 1998).

The cellular events underlying the observed changes in cortical thickness are not well understood. The change in gray matter density may be related to synaptic proliferation and pruning, suggested to be occurring during this age range by postmortem studies (Huttenlocher, 1994). Myelination is also occurring during this period and may result in voxel classification being changed from gray matter to white, producing an apparent loss of gray matter. Indirect evidence in support of this has been reported in cross-sectional studies of normal brain development by Sowell and colleagues (Sowell, Thompson, Tessner, & Toga, 2001) in an independent sample of healthy children and adolescents using similar voxel-based techniques. In this study of 14 children, 11 adolescents, and 10 young adults, gray matter density decrease and volume increase were spatially contemporaneous, potentially supporting the interpretation of changes in cortical thickness as being due to myelination.

Subcortical Gray Matter

In addition to the cortex, there are several gray matter structures in the center of the brain that are grouped under the term "subcortical gray matter." These include the basal ganglia, amygdala, and hippocampus. These structures are crucial components of networks combining different parts of the cortex and the peripheral system for functions such as motor control and emotional responses, many of which

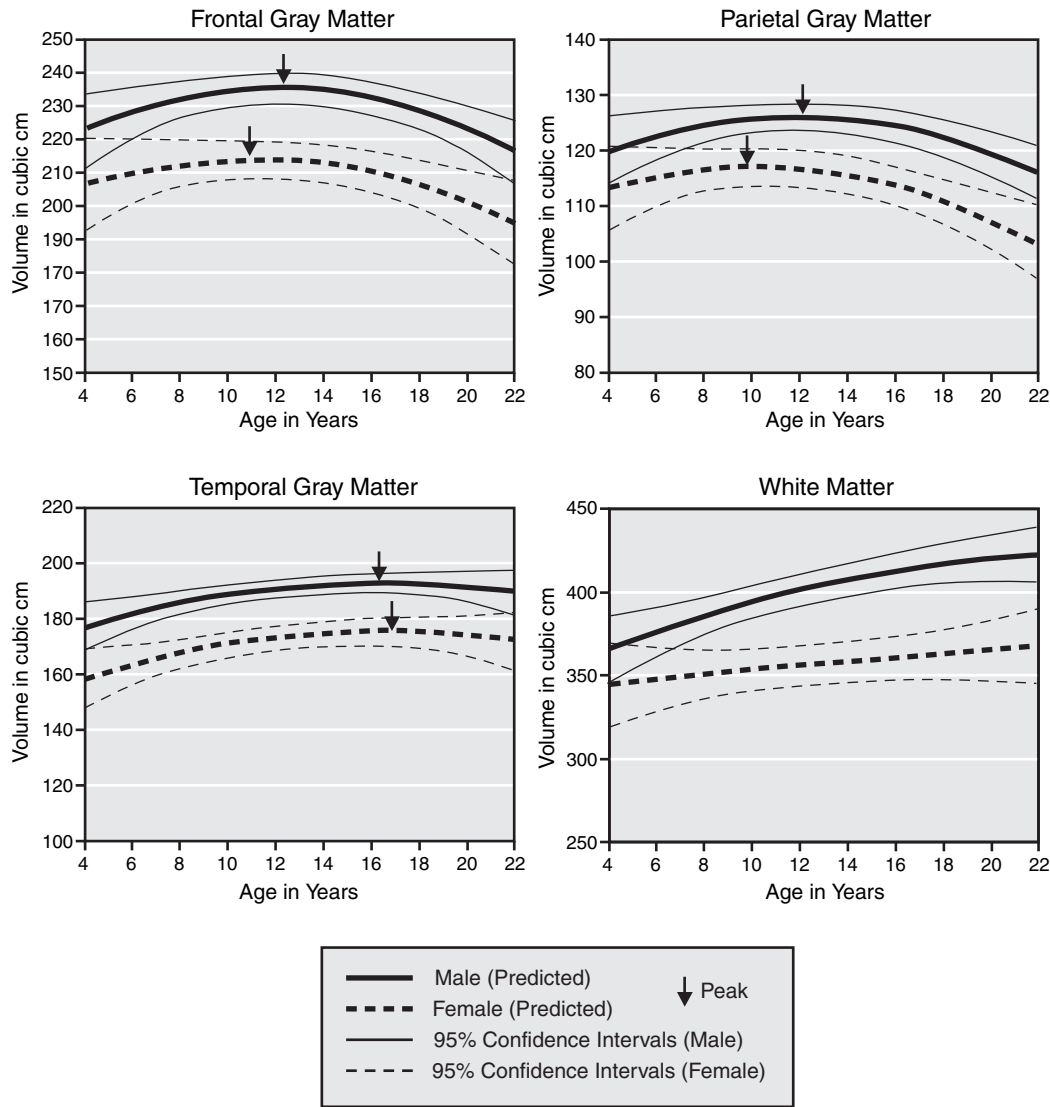

Figure 3.6 Frontal GM, parietal GM, temporal GM, and total WM trajectories: 243 scans from 145 subjects (scans acquired at approximately 2-year intervals). The arrows indicate peak volume.

show significant developmental changes over childhood and adolescence. Because of their often small size and sometimes unclear borders with neighbouring structures, most of them are difficult to quantify using automatic methods and rely on manual tracing techniques.

The basal ganglia consist of the caudate, putamen, globus pallidus, subthalamic nucleus, and substantia nigra. In addition to their central role in control of movement and muscle tone, basal ganglia structures are involved in circuits mediating higher cognitive functions, attention, and affective states. Because of the size and fuzzy border issues mentioned above, only the first three are readily quantifiable by MRI, and at present reliable automated techniques have only been established for the

caudate. Our study found that caudate volume decreases significantly from age 4 to 20 years.

The temporal lobes, amygdala, and hippocampus are integral players in the arenas of emotion, language, and memory (Nolte, 1993). Human capacity for these functions changes markedly between the ages of 4 and 18 years (Diener, Sandvik, & Larsen, 1985; Jerslid, 1963; Wechsler, 1974), although the relationship between the development of these capacities and morphological changes in the structures subserving these functions is poorly understood.

The amygdala and hippocampus have not been quantified for the longitudinal sample. In a previous report from a cross-sectional sample subset of the NIMH sample, amygdala volume increased significantly only in males, and hip-

pocampal volume increased significantly with age only in females (Giedd, 1996). This pattern of sex-specific maturational volumetric changes is consistent with nonhuman primate studies indicating that the amygdala contains high numbers of androgen receptors (Clark, MacLusky, & Goldman-Rakic, 1988) and a smaller number of estrogen receptors (Sholl & Kim, 1989), whereas the hippocampus contains higher amounts of estrogen receptors (Morse, Scheff, & DeKosky, 1986).

Influence of estrogen on the hippocampus is further supported by both rodent and human studies. Gonadectomized female rats have lower density of dendritic spines and decreased fiber outgrowth in the hippocampus, which can be alleviated with hormone replacement (E. Gould, Woolley, Frankfurt, & McEwen, 1990; Morse et al., 1986). In humans, women with gonadal hypoplasia have smaller hippocampi (Murphy et al., 1993). A recent MRI study of 20 young adults also showed proportionately larger hippocampal volumes in females (Filipek, Richelme, Kennedy, & Caviness, 1994).

White Matter

Neurons, glial cells, and myelin are bound by lifelong reciprocal relationships in neural circuits (Fields & Stevens-Graham, 2002). Neurons influence myelin production and the proliferation and survival of oligodendrocytes (Barres & Barde, 2000) in an activity-dependent fashion (Fields, Eshete, Dudek, Ozsarac, & Stevens, 2001); oligodendrocytes secrete neuronal growth factors and influence axonal growth and clustering of ion channels at nodes (Du & Dreyfus, 2002). Oligodendrocytes also support axonal function by means of specific proteins such as CNP and PLP/DM20. Studies of knockout mice deficient in these proteins show aberrant axonal transport and axonal damage in the presence of otherwise normal myelination (Edgar & Garbern, 2004). Later-maturing myelin sheaths, such as those in association tracts and intracortical regions, tend to be thinner with greater axonal load per oligodendrocyte (Kinney, Karthigasan, Borenshetyn, Flax, & Kirschner, 1994; Yakovlev & Lecours, 1967). These characteristics may render later-myelinating areas more vulnerable to environmental or aging-related factors (Bartzokis, 2004).

Regional Volumes of White Matter. Despite their interdependence, developmental curves for WM show significant contrast to the inverted U shaped curve of gray matter (GM). The amount of WM in the brain generally increases throughout childhood and adolescence (see Figure 3.6). Although the rate of increase is age-dependent,

there do not appear to be periods of overall WM reduction for any region within the age range we have examined (Giedd, Blumenthal, et al., 1999). GM volume peaks and then begins to decrease during the 2nd decade, whereas WM volume does not begin to decrease until the 4th decade (Bartzokis et al., 2001). Unlike the regional heterogeneity seen in maturing GM, the slope of increase is approximately the same in the frontal, temporal, and parietal lobes.

Corpus Callosum. The most prominent white matter structure is the corpus callosum, consisting of approximately 200 million myelinated fibers, most of which connect homologous areas of the left and right cortex. The organization of the corpus callosum is roughly topographic, with anterior, middle, and posterior segments containing fibers from their corresponding cortical regions. The functions of the corpus callosum can generally be thought of as integrating the activities of the left and right cerebral hemispheres, including functions related to the unification of sensory fields (Berlucchi, 1981; Shanks, Rockel, & Powel, 1975), memory storage and retrieval (Zaidel & Sperry, 1974), attention and arousal (Levy, 1985), and enhancement of language and auditory functions (Cook, 1986). The relationship between improved capacities for these functions during childhood and adolescence and the noted morphologic changes is intriguing. Several studies have indicated that corpus callosum development continues to progress throughout adolescence (Allen, Richey, Chai, & Gorski, 1991; Cowell, Allen, Zalatio, & Denenberg, 1992; Pujol, Vendrell, Junque, Marti-Vilalta, & Capdevila, 1993; Rauch & Jenkins, 1994; Thompson et al., 2000), raising the question of whether this may be related to the improvement in these cognitive capacities seen during childhood and adolescence. In the NIMH sample, total midsagittal corpus callosum area increased robustly from ages 4 to 18 years.

Diffusion Tensor Imaging, Magnetization Transfer and Relaxometry. The relatively homogeneous appearance of white matter on typical T1 and T2 images after approximately the 2nd year of life does not reflect its highly complex structure and extensive postnatal development. MRI techniques such as relaxometry, MTI, and DTI may be of particular utility to characterize nonvolumetric features of white matter. Changes in T1 and T2 relaxation rates associated with maturation were some of the first findings to be reported using MRI in the 1970s, but then received relatively little attention while investigators focused on describing anatomy based on gray/white contrast.

The growing interest in being able to use neuroimaging techniques to obtain quantitative measures of myelination as an index of brain maturation and in neural circuits as basic anatomic and functional units has led to a surge of studies using newer MR techniques to describe the maturation of myelin and white matter structures.

Neuroimaging studies assessing the maturation of myelination and white matter structures have found results consistent with the available postmortem data. A natural extension of the observation that changes in T1 and T2 contrast during the first 2 years of life could be seen with visual inspection was to derive methods to quantitatively map these relaxation-based developmental changes. Hassink and colleagues (Hassink, Hiltbrunner, Muller, & Lutschg, 1992) compared T2 relaxation values in 9 children and 8 adults and found that T2 values in the frontal lobe decreased with age. The largest decreases were found in the lateral frontal cortex, with smaller decreases in the dorsal frontal cortex, corpus callosum, and head of the caudate. Steen, Ogg, Reddick, and Kingsley (1997) created T1 relaxation maps for 19 children, 31 adolescents, and 20 adults and calculated T1 relaxation in 9 regions of interest in gray and white matter. They found that T1 values changed at different rates in gray and white matter. T1 in white matter reached the mean level for adults by 8 years old in all regions except frontal, which did not reach the mean adult level until 25 years old. The T1 relaxation value did not reach its adult level in cortical gray matter until 20 years old. The difference in T1 relaxation between children and adults was nearly twice as large in gray matter as in white. Both of these papers proposed potential contributors to the changes in relaxation values as including decreased water content, increased myelin, or structural changes.

Several studies of effects of normal development on MT measures have shown MT values increasing with maturation. Engelbrecht and colleagues (Engelbrecht, Rassek, Preiss, Wald, & Modder, 1998) found a threefold increase in myelinating white matter; gray matter during the same period also rose, but only approximately 25%, thought due to myelination within the grey matter. The more marked changes in MT than had been seen in T2 relaxation studies was thought to reflect a contribution from changes in T1 as well. Rademacher and colleagues (1999) assessed MT measures in particular fiber tracts. They obtained MT measures in children age 1, 3, 6, and 30 months in several regions of interest based on fiber tracts determined with a combination of an atlas and postmortem data from 10 adults. They were able to show that MT increased in all regions as a function of age, but that it was higher in projec-

tion and commissural fiber tracts than association tracts. This was consistent with data from the postmortem studies of Yaklovlev and Lecours (1967) and others, who found the myelination process continuing longest in association tracts. Van Buchem et al. (2001) took a slightly different approach, creating a histogram of MTR in each brain tissue voxel to obtain a peak reflective of the MTR values in the brain as a whole. They found that the peak of the histogram both decreased and widened with age, likely reflecting the increasing heterogeneity of the state of myelination in different parts of the brain with maturation, compared to the relatively uniform state at birth.

Studies using DTI have also found regions of the brain to be maturing at different rates. The most marked effects were found in studies of infants, as might be expected from the rapid rates of brain changes seen with other imaging modalities and in postmortem exams during this period. Huppi, Maier, et al. (1998) obtained DTI measures in infants born from 26 to 40 weeks of gestation. They found that central white matter regions showed a significant decrease in the average diffusion constant (ADC), and relative anisotropy (RA) increased in the premature infants toward term. McGraw and colleagues (McGraw, Liang, & Provenzale, 2002) measured mean anisotropy in 66 children with an average age of 16 months to compare maturation in "compact" with "noncompact" areas of white matter. Compact white matter areas were defined as the corpus callosum, internal capsule, and cerebral peduncle, and noncompact areas were defined as frontal-parietal white matter and the corona radiata. They found that mean anisotropy was higher in the compact regions at all ages, although anisotropy values increased more rapidly after birth in the noncompact regions.

Studies of diffusion characteristics early in life have shown how anisotropy can be affected by other characteristics than increased quantities of myelin. McKinstry et al. (2002) found a transient period of increased anisotropy in cortical gray matter between 26 and 31 weeks gestational age, which then disappeared permanently, thought to correspond to a period in which radial glial processes were prominent in the cortex, before dendritic arborization obscured the directional tendency. Another group looked at children age 1 day to 17 years (Morris, Zimmerman, Bilaniuk, Hunter, & Haselgrove, 1999). They found ADC decreased and RA increased rapidly over the first few months. However, these changes occurred prior to the stage at which myelination was known to occur from postmortem studies and before myelin-associated signal was seen on T1- or T2-weighted images. Huppi and colleagues (Huppi,

Warfield, et al., 1998) had also observed that anisotropy increased before onset of myelination. It is currently thought most likely that these changes are due to “premyelination,” the stage in which oligodendroglia are beginning to wrap processes around axons and macromolecule concentrations are increasing in preparation for production of myelin (Prayer & Prayer, 2003; Wimberger et al., 1995).

DTI studies in older children show more subtle findings but also support the presence of continued maturation of white matter structures and myelination. Lovblad et al. (2003) found prolonged changes in ADC in frontal and temporal white matter. Schneider Il'yasov, Hennig, and Martin (2004) studied individuals from birth into their twenties. Although FA levels reached adult levels by 2 years in most regions of the brain, FA was still changing in deep white matter structures in the oldest individuals in their study (Schneider et al., 2004). Olesen and colleagues (Olesen, Nagy, Westerberg, & Klingberg, 2003) combined DTI with functional MRI to determine whether maturing myelination in a given tract would correlate with increased neuronal response in the pertinent cortical regions, and found that FA in the frontoparietal region correlated with the neuronal activity in the superior frontal sulcus and intraparietal lobe.

Summary

Although the total size of the human brain is already maximum size by age 6 (Giedd, Snell, et al., 1996; Sowell et al., 1999; Sowell, Thompson, Holmes, Jernigan, & Toga, 1999), the subcomponents of the brain continue to undergo dynamic changes throughout childhood and adolescence. White matter volume increases linearly, reflecting increasing myelination (Paus et al., 1999) as also supported by findings from modalities such as relaxometry, MTI, and DTI. Cortical and subcortical gray matter volume increases until early to midadolescence before beginning to trend down, presumably from synaptic pruning (Huttenlocher, 1979; Huttenlocher & Dabholkar, 1997), although increasing myelination at the cortical border may also contribute to observed cortical thinning.

The complex relationship between gross structural measures and functionally relevant factors such as neuronal connectivity and receptor density is highlighted by the remarkable degree of variability seen in overall volumes and shapes of individual trajectories in this carefully selected group of healthy children. Healthy, normally functioning children at the same age could have 80% differences in brain volume (Lange, Giedd, Castellanos, Vaituzis, & Rapoport, 1997; see Figure 3.4).

STUDIES OF ATYPICAL DEVELOPMENT

Information about normal and atypical development is mutually informative. Normal data is necessary to interpret findings from clinical populations, but the opportunity provided by illness to see how structure and function change together under the influence of pathology provides an invaluable window into their relation in healthy individuals as well. Studying pediatric populations adds the dimension of developmentally related changes in structure and function as both another complexity to account for and a target for understanding.

An enormous amount of work has been done in using neuroimaging to explore the changes in brain structure associated with neuropsychiatric disorders, although the amount of attention paid to any particular disorder varies widely. The extent of neuroimaging studies being performed in pediatric populations has lagged behind the equivalent studies in adults. This is in large part because of added complications of doing imaging studies in children, ranging from the ethical issues of performing research with children, to the lower tolerance of children for scanning procedures, to the technical issues peculiar to pediatric populations, such as smaller head sizes and age-related differences in tissue MR properties. Even so, the accelerating number of studies being performed in younger populations has made a completely comprehensive review not feasible within the scope of a single chapter; and we have, therefore, chosen to cover a subset of illustrative or common neuropsychiatric disorders affecting children and adolescents.

We have grouped the disorders in this section into three broad categories. The first consists of disorders with identified specific genetic or environmental etiologies. While there is an enormous potential catalogue of such disorders, relatively few actually have been the subject of significant neuroimaging studies in pediatric populations. For this group we have selected Fragile X, Rett Disorder, Fetal Alcohol Spectrum Disorders (FASD), and Posttraumatic Stress Disorder (PTSD), as relatively common disorders which demonstrate some of the complexity of the observed effects of even known genetic or environmental perturbations on trajectories of brain development. The second and third groups cover the most common neuropsychiatric disorders affecting children and adolescents, divided by typical age of onset: Autism, dyslexia, ADHD, and obsessive compulsive disorder (OCD) as disorders usually first seen in childhood, and Schizophrenia and mood disorders as disorders whose incidence begins to markedly increase during puberty and adolescence. Tables are provided with details

about studies for those disorders with a relatively sizeable literature.

Disorders Associated with Known Genetic or Environmental Factors

A standard experimental method in developmental biology is to introduce a mutation or pathogen during the developmental process and observe how the course of development is altered (S. F. Gilbert, 2003). Neurodevelopmental disorders with known genetic or environmental etiologies provide an analogous opportunity in humans. Progress in genetic analysis methods is providing an increasingly large list of such disorders, allowing the opportunity to see how a specific perturbation impacts growth on multiple levels in a human subject.

Although studies in humans are still complicated by the often late identification of the illness and multiple other confounding factors, the identification of known etiological factors makes it feasible to develop animal models of the corresponding environmental or genetic abnormality and prospectively map their effect on the

course of brain development from much earlier stages and in a more controlled fashion. In addition, methods such as biopsy and postmortem study can be incorporated into animal studies and then correlated with less invasive measures, such as imaging data, providing important opportunities to understand how given abnormal tissue features may appear using the less invasive methods feasible for use in human studies.

If the brain is conceptualized as containing different levels of organization, abnormalities arising from known genetic abnormalities can be thought of as illnesses in which one starts at the bottom and strives to work one’s way forward through the chain of causality to understand how the observed abnormalities of function are produced, in contrast to clinical disorders where one is attempting the much more difficult inverse solution (Courchesne, Townsend, & Chase, 1995). Therefore, despite the relative rarity of these disorders compared to clinical syndromes such as depression and psychosis, their potential to help unravel the relationship of genetic or environmental abnormalities to the clinical syndromes that impact functioning of individuals and society is invaluable (see Figure 3.7).

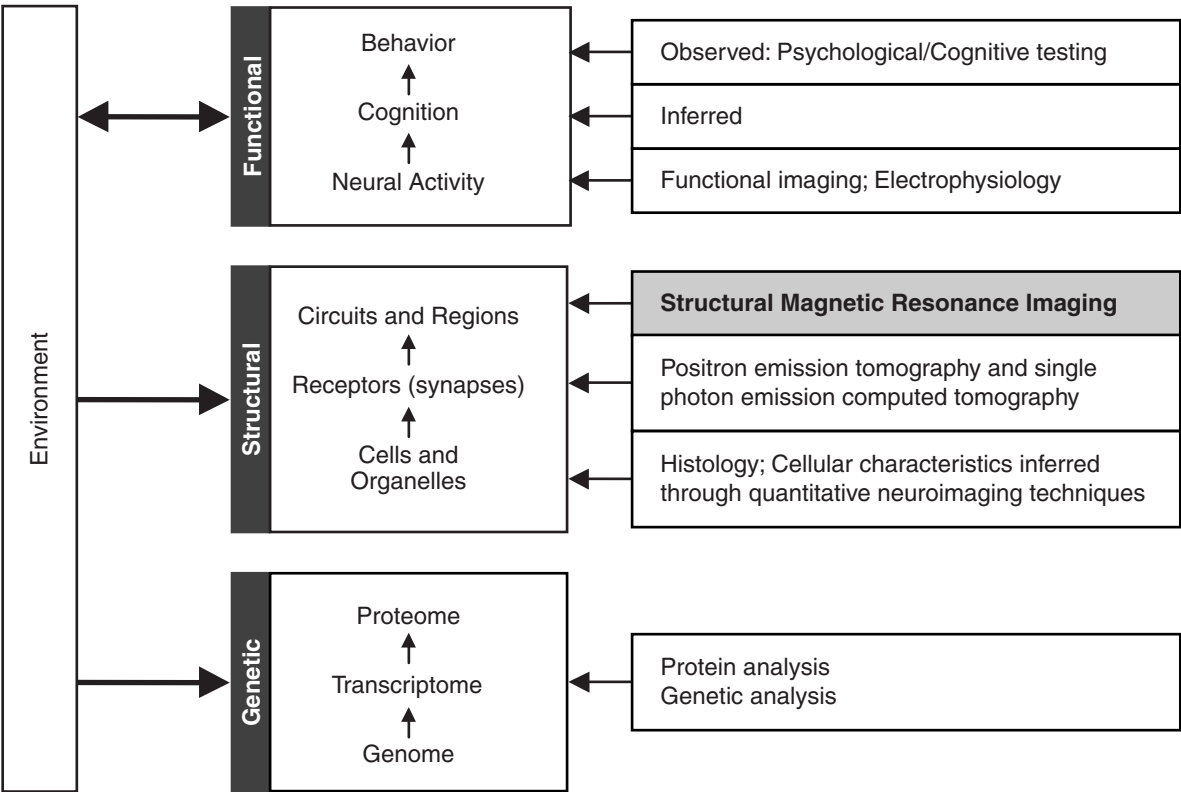

Figure 3.7 Model delineating different levels of analysis (from gene to behavior) in a causal framework. Use of this model highlights the contribution of structural neuroimaging to better understanding both typical and atypical development.

Fragile X Syndrome

Fragile X syndrome is the most common heritable cause of a developmental neuropsychiatric disorder with known genetic etiology, and second only to trisomy 21 (Down syndrome) as a genetic cause of mental retardation (Crawford et al., 1999; Freund, Reiss, & Abrams, 1993). The characteristic physical features associated with Fragile X syndrome include a long narrow face, large ears, prominent jaw, and macro-orchidism. These may become apparent only after puberty. Males, having only one X chromosome, tend to suffer more severe impairments than females, who are heterozygous for the affected X chromosome. Most males are affected with a moderate to severe degree of mental retardation; cognitive deficits in females include mild mental retardation and learning disabilities. Both sexes have a similar pattern of cognitive deficits, including impairment in short-term and working memory, visuospatial abilities, language, and executive function. The behavioral features can overlap significantly with Autistic Disorder, including poor socialization, gaze avoidance, stereotypic behavior, and unusual responses to sensory stimulation. Attention deficits and pronounced anxiety are also frequently present (Hessl, Rivera, & Reiss, 2004).

The genetic abnormality responsible is an expanded trinucleotide repeat on the X chromosome, within a gene called the Fragile X mental retardation I gene FMR1. The name Fragile X arose from initial observations of an abnormally thin region of the affected chromosome. The promoter region for this gene normally contains a CGG triplet repeat region up to 55 repeats long (Hessl et al., 2004). When the number of repeats increases to over 200, the promoter region is hypermethylated and transcription of the gene's product is repressed, resulting in the classic "full mutation" form of Fragile X. The phenotype can vary widely depending on factors such as the degree of hypermethylation, the degree of skewing of the X chromosome in females, and the presence of cellular mosaicism in degrees of triplet expansion.

Individuals with between 55 and 200 repeats have what is called the "premutation" form, which is associated with an increased risk of the full mutation appearing in the next generation. The premutation form appears to also have other functional and pathological impacts (C. J. Moore, Daly, Schmitz, et al., 2004; C. J. Moore, Daly, Tassone, et al., 2004). Approximately 25% of individuals with the premutation have an attenuated form of the typical Fragile X syndrome. In addition, a subgroup of previously normally functioning individuals has been identified who develop a clinically heterogeneous move-

ment disorder later in life called Fragile X associated tremor/ataxia syndrome (FXTAS; Jacquemont et al., 2004), and women with the premutation have a 15% to 34% chance (Welt, Smith, & Taylor, 2004) of premature ovarian failure. Neither of these conditions is seen in individuals with the full mutation. The reasons for this are not clear, but it has been found that the repeats in the premutation form are not hypermethylated, but instead may be associated with an overexpression of FMR1 mRNA. The recognition of the potential clinical relevance of the premutation form has population implications, as it is much more prevalent than the full mutation (Moore, Daly, Schmitz, et al., 2004).

There have been several neuroimaging studies of Fragile X syndrome, although studies available to date have been cross-sectional in nature and often limited by small sample size (see Table 3.1). The initial studies by Reiss and colleagues (Reiss, Aylward, Freund, Joshi, & Bryan, 1991; Reiss, Freund, Tseng, & Joshi, 1991; Reiss, Lee, & Freund, 1994) at the Johns Hopkins Pediatric Neurodevelopmental Disorders Clinic compared males and females with the full mutation to scans from an archive of age-matched controls who were either healthy siblings of participants in the program who did not have Fragile X or subjects who had received scans for clinical reasons that were read as normal. They reported that both males and females showed decreased size of the posterior cerebellar vermis, increased fourth ventricle volume, and increased size of the hippocampus bilaterally. The finding of hippocampal enlargement was replicated in a small study by Kates, Abrams, Kaufmann, Breiter, and Reiss in 1997. They did not find any correlation of imaging findings with cognitive or behavioral measurements.

A larger follow-up study in 1995 found the caudate to be enlarged in the Fragile X group, and the amount of enlargement correlated with the degree of FMR1 methylation (Reiss, Abrams, Greenlaw, Freund, & Denckla, 1995). In addition, these authors reported that whereas caudate volume had a direct correlation with IQ in controls, it had an opposite inverse correlation in patients, suggesting that the mechanism for caudate enlargement could be different in the two groups. A relatively large caudate was also seen in a pediatric subset of this group (Eliez, Blasey, Freund, Hastie, & Reiss, 2001).

Mazzocco, Kates, Baumgardner, Freund, and Reiss (1997) compared sagittal measurement of the cerebellar vermal lobes VI and VII in 30 females with Fragile X and 32 controls. They found that the vermis was smaller in the Fragile X group; they also reported a negative correlation between the size of the vermis and the degree of autistic-like

TABLE 3.1 Structural Neuroimaging Studies of Fragile X Disorder

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Reiss, Aylward, Freund, Joshi, & Bryan (1991)	14 Males (15.7, 2–43)	17 DD Males (11.1, 3–42) 18 ND males (12.5, 1–32)	T1, 5 mm sag with 1– 2.5 mm gap; 3 mm axial slices no gap; manual ROI; areas measured from midsag slice, vol- umes from axial.	FX had dec. volume post cerebellar vermis, inc. volume 4th vent com- pared to controls, DD not different than controls.	DD = Developmental disability, IQ < 80. ND = Normally developing, IQ > 80, controls include normal volunteers and non-FX clinical populations.
Reiss, Freund, Tseng, & Joshi (1991)	12 Females (14.2, 6–27)	12 Females (12.9, 5–27)	T1, 5 mm sag with 1– 2.5 mm gap; 3 mm axial slices no gap; manual ROI; areas measured from midsag slice, vol- umes from axial.	FX: areas of post cere- bellar vermis VI and VII smaller, larger 4th vent volume.	Controls include normal volun- teers and non-FX clinical populations.
Reiss, Lee, & Freund (1994)	6 Males 9 Females (12.9 \pm 6.3)	2 Males 6 Females (10.3 \pm 4.9)	T1 sagittal 3–5 mm contiguous slices, axial, T1 coronal 3 mm slice thickness, manual ROI of volumes.	Hippocampi larger in FX bilaterally, inc. with age in FX, R and L sup temp gyrus dec. with age in FX, no group \times gender or gender effect.	Controls include normal volun- teers and non-FX clinical popu- lations; no correlation of volumes with cognitive mea- sures; hippocampi volumes were not controlled for overall brain size; cross-sectional study.
Reiss, Abrams, Greenlaw, Freund, & Denckla (1995)	31 Female FX, 2 female PM (11.3 \pm 4.4) 17 Male FX (10.7 \pm 8.4)	70 Females (11.1 \pm 3.6) 29 ND males (11.9 \pm 7.5) 21 DD males (11.0 \pm 9.6)	T2 axial 5 mm slices with 0–2.5 mm gap, manual ROI of areas and volumes.	Females: FX larger cere- brum, caudate, thalamus. Males: FX larger cau- date, DD smaller than controls, lateral vent larger in FX, corr with IQ, caudate volume inc. with dec. gene activation.	Not all subjects had all MRI measures available due to scan quality. Study also included case study of monozygotic female twins with FX discor- dant for MR.
Jakala et al. (1997)	7 Male FX (29.1 \pm 11.0) 9 Male PM (52.4 \pm 19.7) 9 Female FX (34.2 \pm 15.8) 9 Female PM (48.3 \pm 15.0)	10 each, matched on age and sex (from archive)	T1, 2 mm coronal con- tiguous slices, manual ROI.	PM tend to smaller hippocampi than con- trols, FX not different than PM.	PM = Premutation form; hip- pocampal volumes normalized for total brain volume.
Kates, Abrams, Kaufmann, Breiter, & Reiss (1997)	6 Males 4 Females (7.1 \pm 4.7)	2 Males 5 Females (8.9 \pm 2.4)	MRI, manual ROI.	FX hippocampus larger.	Study compared different meth- ods of measuring hippocampal volume.
Mazzocco, Kates, Baumgardner, Freund, & Reiss (1997)	28 Females (10.6 \pm 3.2)	31 Females with LD or siblings of probands (10.3 \pm 2.8)	T1, 5 mm sag with 1–2.5 mm gap, manual ROI; areas measured from midsag slice.	Some behavioral impair- ment corr with smaller VI+VII area and with AR.	LD = Learning disability; AR = Activation ratio; reflect number of cells with normal X chromo- some; same subjects as in Reiss (1991) with additional measure of FMR1 gene expression.
Mostofsky et al. (1998)	32 Males (11.1, 1–43) 37 Females (11.4, 4–28)	28 Males with CD (9.2, 2–42) 38 Males (ND) (12.5, 1–44) 53 Females (11.3, 3–26)	T1, 1–5 mm sag with 0–1.5 mm gap, 1.5 mm coronal contiguous slices, manual ROI; areas measured from midsag slice.	Males: FX PV smaller than CD or ND. FX IC larger than CD but not ND. Females: PV smaller, not as diminished as in males. PV size corr with several cognitive measures.	CD = Cognitive disability (IQ < 80); ND = Normal development; PV = Posterior vermis; IC = Intracranial area; control subject MRIs from either documented or clinically probable non-FX sub- ject, 11 FX; and 10 of compari- son groups also met criteria for Autism; medication status not controlled. Post. vermis size not correlate with age; interpreted as most likely hypoplasia.

TABLE 3.1 Continued

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Murphy et al. (1999)	8 Females with premutation (39 \pm 9)	32 Females (39 \pm 10)	8 FX/20 controls had scans on .5 T scanner, 7 mm contiguous axial slices; 6/11 scanned on 1.5 T for hippocampal mea- sures, 5 mm contiguous coronal slices, manual ROI.	FX: Smaller overall brain size, caudate, and thalamus; larger hip- pocampi.	Volumes adjusted for intracra- nial volume. PET study also performed found abnormalities of metabolism in multiple areas.
Eliez, Blasey, Freund, Hastie, & Reiss (2001)	27 Females 10 Males (10.2 \pm 3.8)	64 Females (10.6 \pm 2.9) 21 Males (10.7 \pm 2.8)	T2/PD axial 5 mm con- tiguous slices, seg- mented, manual ROI of volumes.	Caudate and ventricles larger in F, thalamus larger in FX females only.	Subjects subset of a larger study (Reiss, 1995).
Kates, Folley, Lanham, Capone, & Kaufmann (2002)	21 Full mutation FX: (4.89 \pm 1.7) 12 Mosaic FX (4.96 \pm 1.3) 15 DLD (5.18 \pm 1.2) 12 Down syn- drome (5.94 \pm 1.6)	8 Males (5.79 \pm 1.7)	T1, 1.5 mm contiguous slices, semiautomatic segmentation and par- cellation in lobes based on Talairach grid.	All groups had smaller gm and wm temp lobe volumes, FX no differ- ence in overall brain size, DS all volumes smaller and marked neg- ative correlation of vol- ume with age, DLD and DS smaller parietal wm volume.	All subjects male DLD = Developmental language delay.
Barnea-Goraly et al. (2003)	10 Females (16.7 \pm 3.82)	10 Females (17.1 \pm 3.82)	DTI: 6 directions, 5 mm slices/1 mm skip, not include inferior cerebel- lum, measure FA.	FX showed reduced FA frontal-caudate white matter on L, trend on R; dec. in sensory-motor regions bilaterally.	FA: fractional inosotropy; IQ and FA measures correlated within FX; but these regions were not the same as those which differed between groups.
Kaufmann et al. (2003)	10 ideopathic Autism (7.0 \pm 2.4), 27 DS (7.2 \pm 2.1), 11 DS plus Autism (7.0 \pm 1.8), 9 FX (5.3 \pm 1.1), 13 FX plus Autism (5.7 \pm 2.1)	22 Males (8.3 \pm 1.9)	T1 scans, slice thick- ness range from 3–5 mm, gap range from 0–1.0 mm, manual ROI of midsagittal areas, report ratio of vermis areas to total intracra- nial area to account for DS smaller IC.	Idiopathic Autism: smaller ratio VI-VII/IC, DS: smaller IC, decreased posterior ver- mis, DS+Autism all ver- mis smaller; FX dec. posterior vermis, FX+Autism trend to higher ratio VI-VII.	All subjects were male. DS = Down syndrome; IC= Intracra- nial area; 4/16 DS boys also diagnosed with childhood disintegrative disorder.

features in this population, and that the vermis was relatively larger in girls who had a higher proportion of activated normal X chromosomes.

Kates, Folley, Lanham, Capone, and Kaufmann (2002) and Kaufmann et al. (2003) compared cerebellar measures in Fragile X against other neurodevelopmental disorders in addition to healthy controls; Kates, Folley, et al. included developmental language disorder and Down syndrome, and Kaufmann et al. included Down syndrome and Autism. Kates, Folley, et al. found significant age-related decreases in Down syndrome but not in Fragile X; all three disorders had smaller temporal lobes. Kaufmann et al. looked only at a midsagittal slice; they found that the vermis was smaller in Fragile X and in idiopathic

Autism, but the group with Fragile X and Autism had larger cerebellar lobes VI-VII.

One study has been reported to date looking at white matter structure in Fragile X using DTI; Barnea-Goraly and colleagues (2003) compared fractional inosotropy in 10 females with the full mutation with 10 matched controls. They found significantly lower fractional inosotropy in areas connecting the left frontal and caudate, and right and left sensorimotor regions; fractional inosotropy in the right frontal-caudate region was lower but did not reach significance. They interpreted the abnormalities in the sensorimotor region as being consistent with findings of sensory abnormalities and stereotypic behavior, and the frontal-caudate with problems in executive function, impulsivity,

and hyperactivity. FMRP is not typically found in the axons, but they hypothesized that abnormalities in the target neuron cell bodies and dendrites could impact the creation of axonal tracts during development and their maintenance afterward.

The recognition that the premutation form may also be associated with abnormalities has increased interest in exploring how the premutation form may affect brain structure. A 1999 study using manual parcellation in females with the premutation form reported decreases in overall brain size and bilateral caudate and thalamic nuclei and an increase in bilateral hippocampal size (Murphy et al., 1999). This study also performed PET imaging and reported hypometabolism in the right parietal, temporal, and occipital association areas, and bilateral hypermetabolism in the hippocampi and left cerebellum. No correlations were found between brain measures and IQ. A later study by the same group with men with the premutation form using voxel-based methods found decreases in gray matter density in the regions including the cerebellum, thalamus, and amygdala-hippocampal complex, and decreased white matter density in the cerebellum, brain stem, pons, cingulate and genu of the corpus callosum, and tracts in the temporal and frontal lobes (Moore, Daly, Tassone, et al., 2004). They again found no correlation of any brain measures with IQ.

Fragile-X associated tremor/ataxia syndrome (FXTAS) is considered to be a different disorder, arising through a different mechanism from an abnormality in the same gene which results in a gain-of-function abnormality through excess production of mRNA rather than the loss of function of the full mutation developmental disorder. The neuropathological findings in FXTAS are distinct from those in the neurodevelopmental form of Fragile X, taking the form of eosinophilic inclusions rather than abnormal dendrite morphology. Clinical MRI of men with FXTAS have shown a high number of individuals with bilateral T2 hyperintensities in the cerebellum, although this is not specific to FXTAS (Brunberg et al., 2002). FXTAS has only recently been identified in women, and neuroimaging studies are not yet available (Hagerman, Levitt, et al 2004).

FMRP1 encodes for a protein called the Fragile X mental retardation protein (FMRP; Tassone et al., 1999). FMRP is primarily found in the cell body, dendrites, and synapses. It may be particularly important in the formation of dendrites and regulation of synaptic development and in response to environmental stimulation (Darnell et al., 2001; Greenough et al., 2001; Willemsen, Oostra, Bassell, & Dichtenberg, 2004). Postmortem examination in both individuals with the full mutation of Fragile X and FMRP

knockout mice has revealed the presence of morphologically immature neurons with abnormally long and thin dendritic spines and elevated spine numbers, similar to what is seen early in development and in animals with sensory deprivation (Hinton, Brown, Wisniewski, & Rudelli, 1991; Irwin, Galvez, & Greenough, 2000). Expression of FMRP has been found to increase in animal models following environmental stimulation or motor activity (Todd & Mack, 2000; Todd, Malter, & Mack, 2003). Fragile X syndrome is a neurodevelopmental disorder arising from an unstable trinucleotide repeat. It shows dosage effects associated both with the degree of expansion and its association with the X chromosome. Although the studies described here provide some important first steps toward comparing neurodevelopmental disorders directly, their methodologic limitations affect the conclusions that can be drawn. Given the nonspecific nature of cerebellar abnormalities and hippocampal abnormalities, it would be valuable to compare cerebellar differences with dosage effects, including premutation and full mutation.

Rett Syndrome

Rett syndrome is a pervasive X-linked developmental disorder first identified by Andreas Rett in 1965 (Rett, 1966). The classic presentation is almost exclusively seen in females, affecting approximately 1:10,000. It is the second most common cause of mental retardation in females after Down syndrome (Hagberg, 1995). Called by some "the paradigmatic neurodevelopmental disorder," Rett syndrome is of particular interest because of its unusual course. During the first 6 to 18 months of life, children apparently develop normally. Retrospective studies of videotapes made of children later diagnosed with Rett syndrome have shown specific patterns of abnormal motor activity during this time, suggesting that neurologic abnormalities are present, if not yet of clinical severity (Einspieler, Kerr, & Prechtl, 2005). A severe deterioration then sets in, classically moving through stages including deceleration of head growth, behavioral regression, autistic features, loss of language and hand use, onset of autonomic and motor abnormalities, and the classic hand-wringing sign. Seizures and sometimes severe mental retardation also frequently are present. However the deterioration then stops, usually by the mid-teens, and a stable state ensues that can last decades (Naidu, 1997; Neul & Zoghbi, 2004). There is a high degree of clinical heterogeneity, so far appearing to be related both to various forms of MeCP2 mutations and to different patterns of X-chromosome inactivation (Akbarian, 2003; Neul & Zoghbi, 2004).

TABLE 3.2 Structural Neuroimaging Studies of Rett Syndrome

Study	Patients (Mean Age \pm SD, or Range)	Controls	Method	Findings	Comments
Casanova et al. (1991)	8 Females (5.3, 3–10)	10 Females (7, 4–10)	Area and shape for hemisphere, cc, mid-brain, pons, lobes I-V and VI-VII cerebellum, head of caudate; area measured from slice.	Dec. area for cerebrum, L and R caudates.	
Murakami, Courchesne, Haas, Press, & Yeung- Courchesne (1992)	13 Females (12.0 \pm 6.3)	10 Females (15.4 \pm 7.5)	MRI, ROI area measured from single slices (which areas?).	Dec. volume cerebrum.	
Reiss et al. (1993)	11 Females (10.1 \pm 5.2)	15 Females (11.2 \pm 2.5)	MRI, ROI analysis of volumes.	Dec. volume cerebrum; more gray matter loss than white, most in frontal and caudate.	No correlation of dec. volumes and duration of illness.
Subramaniam, Naidu, & Reiss (1997)	20 Females (9.74, 3–23)	20 Females (9.03, 3–23)	MRI, ROI analysis of volumes.	Dec. volume cerebrum, caudate.	Extension of 1993 study to larger group.
Dunn et al. (2002)	9 Females (18.4, 14–26)	9 Females (23.2, 20–29)	MRI, ROI analysis of volumes.	Dec. vol. caudate.	PET scans also performed.

The earliest MRI studies of girls with Rett syndrome compared cross-sectional areas of different brain regions (see Table 3.2). Casanova et al. (Casanova et al., 1991) compared eight girls with Rett syndrome, aged 3 to 10, with 10 age- and sex-matched controls. They measured sagittal cross-sections of several structures including whole brain, corpus callosum, and cerebellum, and horizontal cross-sections of the caudate nuclei. Their findings included smaller volumes for total brain and for caudate nuclei, which trended toward being even smaller than expected when correcting for the smaller overall brain volume. Murakami examined 13 girls with Rett syndrome aged 5 to 25 and 10 controls aged 6 to 27, and found decreased volumes of total cerebrum, cerebellum, caudate nuclei, and brainstem and increased volume in the fourth ventricle. They also observed that the cerebellum and fourth ventricle appeared to be more severely affected in the older Rett syndrome girls, which they interpreted as due to increasing cerebellar atrophy with age; this effect was not seen in the supratentorial structures (Murakami, Courchesne, Haas, Press, & Yeung-Courchesne, 1992).

Reiss et al. (1993) also reported potentially age-related changes in a volumetric study of 11 Rett syndrome girls aged 5 to 15 with 15 matched controls, in that the brains of girls at the beginning of the illness course were more similar to those of controls than older girls, and that decrease in brain size did not appear to continue past a certain

point. In their study the frontal region was more affected than other brain regions and gray matter more than white matter. An extension of this study in which sample sizes had been increased to 20 subjects and 20 controls found that gray matter was most reduced in the prefrontal, posterior frontal, and anterior temporal regions, while white matter was more uniformly decreased. Caudate nuclei were disproportionately smaller even after accounting for the overall smaller cerebral volume in the Rett syndrome subjects (Subramaniam, Naidu, & Reiss, 1997).

Neuropathological findings are subtle but pervasive, consistent with the imaging results. Postmortem brain volume has been found to be 14% to 34% smaller than girls of the same age and is relatively smaller even when matched for the smaller body size commonly seen in Rett's syndrome (Armstrong, 1992; Armstrong, Dunn, Antalffy, & Trivedi, 1995). Histologic studies have found reduced dendritic length and complexity in pyramidal neurons of the frontal and motor cortex, and neurons in widespread other areas of the brain are smaller and more densely packed. Multiple other abnormalities have been found in different regions of the brain in girls with Rett's syndrome. For more information, the reader is referred to the recent review by Jellinger (2003).

The low rate of familial cases of Rett syndrome delayed identification of the responsible genetic abnormality until 1999, when Amir and colleagues (1999) showed that most

cases of Rett syndrome were associated with mutations in an X-linked gene called *MECP2*, which encodes for protein methyl cytosine-binding protein 2 (MeCP2). Since that time, genotyping of males in affected families has shown that the mutation is not exclusive to females, but that males tend to have a much more severe phenotype, which is often fatal early in life (Neul & Zoghbi, 2004).

The identification of MeCP2 has stimulated rapid advances in exploration of its function in Rett syndrome and in normal development, largely through animal models in which MeCP2 is impaired in different ways or at different stages of maturation. MeCP2 is a protein that suppresses gene expression through methylation of transcription factors. Using animal models, it has been possible to show that MeCP2 appears to be most active in neurons, rather than other somatic cells. In addition, elegant work by Shahbazian et al. (2002) has demonstrated that MeCP2 expression becomes detectable as neurons reach a particular stage of maturity. This delayed activity of the affected protein provides an exquisite example of how a genetic abnormality may impact the developmental course during a specific postnatal period. Early developmental milestones, such as neurogenesis and migration, appear relatively unaffected, while the later tasks of synaptogenesis and maintenance are impaired. This is consistent with the MRI findings of generalized volume deficits, most pronounced in gray matter, and the associated neuropathological findings of decreased volume and insufficient neuropil in the absence of more striking regional abnormalities. It should be noted that we have chosen not to cover the studies of neurotransmitter function in Rett Disorder as outside the scope of the chapter, but these studies support the presence of functional abnormalities on the synaptic level. Examples of more detailed recent reviews include Neul and Zoghbi (2004) and Segawa and Nomura (2005).

Fetal Alcohol Syndrome

Although concerns that parental alcohol use may have a potential adverse impact on children have been mentioned in the literature for centuries, alcohol was not identified as a teratogen associated with a specific pattern of deficits until a case series of abnormalities in 127 children born to alcoholic mothers was described by a physician in Belgium in 1968 (Lemoine, 1968; Randall, 2001). The report did not attract much notice until Jones and Smith (1973; Jones, Smith, Ulleland, & Streissguth, 1973) independently described a similar group in 1973, also coining the term Fetal Alcohol Syndrome and proposing a set of diagnostic

criteria. The deficits described by both groups included growth retardation, physical malformations, a distinctive pattern of facial anomalies, decreased head size, and central nervous system damage as evidenced by low IQ and behavioral problems.

Further study of the disorder was complicated by the recognition that prenatal alcohol exposure could result in a range of presentations, not all of which exhibit the typical physical stigmata. Some variants, such as Alcohol-Related Neurodevelopmental Disorder (ARND), have no visible physical abnormalities, but cognitive and behavioral problems equally as severe as FAS. These variants are currently all included under the label Fetal Alcohol Spectrum Disorders (FASD; Hoyme et al., 2005), of which the classic FAS is the most severe. The variety of presentations has also made assessment of the prevalence of FASD difficult (Hoyme et al., 2005; Sampson et al., 1997). The need to document prenatal alcohol exposure as part of the diagnosis is often challenging, as mothers are aware of the associated stigma and may not be forthcoming. Estimates currently vary from 0.5 to 1 per 1,000 live births, with some communities showing much higher rates, often associated with disadvantaged socioeconomic status (May, Brooke, et al., 2000; May & Gossage, 2001). Sampson and colleagues performed a critical analysis of available incidence estimates for FAS and presented new estimates for both FAS and ARND. Their estimates for FAS were 2.8/1,000 in a middle-class community and 4.6/1,000 in a high-risk population, and a combined risk for FAS and ARND in the Seattle community of 9.1/1,000 (Sampson et al., 1997).

Attempts to understand the relationship of prenatal alcohol exposure to the observed disabilities has been complicated by the many other factors that may accompany maternal alcohol use and also affect prenatal development, such as access to prenatal care, maternal nutrition, and potential polysubstance use (Randall, 2001). In addition, the amount and timing of alcohol use can have a critical impact on outcome, and this information is rarely available in clinical studies (Olney et al., 2002; Streissguth, Sampson, Barr, Clarren, & Martin, 1986). Early postmortem studies showed marked structural brain abnormalities, but these may have been confounded by their primarily being performed in children with pronounced morbidity (Randall, 2001; Riley, McGee, & Sowell, 2004).

Advent of neuroimaging has allowed assessment of brain changes in less severely affected children, although difficulty controlling for dosage and timing effects is still prob-

lematic. Although severely affected children can show striking brain abnormalities, the most consistent finding is overall smaller cerebral volume in the presence of Microcephaly (see Table 3.3). Preliminary results from the neuroimaging studies have additionally found some regions to be disproportionately decreased in size, including the cerebellum and caudate (Archibald et al., 2001; Autti-Ramo et al., 2002; Sowell, Thompson, Mattson, et al., 2002; Swayze et al., 1997). The corpus callosum also appears to be impacted in a majority of cases, in keeping with generally prominent effects of alcohol exposure on development of midline structures (Autti-Ramo et al., 2002; V. P. Johnson, Swayze, Sato, & Andreasen, 1996; Sowell, Mattson, et al., 2001; Sowell, Thompson, et al., 2001; Swayze et al., 1997).

Animal models in which dosage and timing can be controlled are particularly important and have shown distinct effects on different brain regions at different periods (Olney et al., 2002). Impact of blocking NMDA receptor has been informative regarding the role of NMDA function in normal development, used in theories of other illnesses such as Schizophrenia (Olney, Newcomer, & Farber, 1999).

An important element of future neuroimaging studies of the effects of prenatal alcohol exposure will be more exploration of white matter structure, as work to date has implicated this as a particularly affected region (Bookstein, Sampson, Connor, & Streissguth, 2002; Roebuck, Mattson, & Riley, 2002; Sowell, Mattson, et al., 2001). There has also been some interesting work in animal models studying how the genetic background of the exposed fetus interacts with prenatal alcohol exposure to affect the severity of the resultant dysmorphic features (Su, Debelak, Tessmer, Cartwright, & Smith, 2001).

Posttraumatic Stress Disorder

PTSD is a specific set of symptoms associated with exposure to an extreme traumatic stressor. Research of PTSD in children began in the 1980s, when it was recognized that children report a wide range of reactions following trauma (Yule, 2001). Like adults, children can have symptoms of reexperiencing traumatic events, avoidance, numbing, and increased physiological arousal. Sleep disturbances, fear of the dark, and nightmares are common. Particularly in very young children, reaction to trauma may be more clearly exhibited through alterations in behavior, such as play centered around traumatic events or loss of previously acquired skills, social withdrawal, numbing, and antisocial behaviors. There is considerable comorbidity with depression, anxiety, and pathological grief reactions.

Little is known about the prevalence of PTSD in children, and rates from high-risk children vary widely. About 25% of children who experience road traffic accidents and 10% of children admitted to hospital after falls develop PTSD (Bryant, Mayou, Wiggs, Ehlers, & Stores, 2004; Heptinstall, 1996; Stallard, Salter, & Velleman, 2004). Biological findings in PTSD are compatible with those of a chronic stress response, with some suggestive differences; most notably, cortisol levels in PTSD are lower but show a greater dynamic range. It has thus been suggested that PTSD may be associated with hyperreactivity in the hypothalamic-pituitary-adrenal axis, leading to secondarily reduced cortisol levels through negative feedback (Yehuda, 2001).

Imaging studies of adults with PTSD have focused on combat veterans and adults with a history of sexual childhood abuse (Hull, 2002). Most (but not all) studies demonstrated a reduced volume of the hippocampus in affected subjects (Bremner et al., 1995, 1997; Gurvits et al., 1996; Myslobodsky et al., 1995; Stein, Koverola, Hanna, Torchia, & McClarty, 1997). Nonspecific white matter lesions have also been reported (Canive et al., 1997). Based on these findings, Bremner (1999) and Sapolsky (1996) postulated that stress results in long-term damage in brain structures and leads to symptoms of PTSD. According to this hypothesis, the smaller hippocampus of patients is due to the toxic effect of glucocorticoids on this particularly vulnerable brain structure. However, as noted earlier, cortisol levels are often lowered in PTSD.

In their seminal studies of children with PTSD, DeBellis et al. (1999) did not find hippocampal changes as predicted by the studies in adults. However, the affected children showed smaller intracranial and cerebral volumes than matched controls. Specific regions in the PTSD group also showed differences: The corpus callosum was smaller and the lateral ventricles proportionally larger than in controls. They also found differences in the volumes of white and gray matter of the superior temporal gyrus (De Bellis et al., 2002). To some extent, the findings differed between boys and girls: The corpus callosum effects were more marked in boys, and females had a larger cerebral volume reduction. Interestingly, a smaller corpus callosum has also been shown in children who experienced childhood neglect and, in particular, sexual abuse, a condition strongly predictive of PTSD. Because these corpus callosum changes were neither observed in healthy controls nor in children with other psychiatric disorders, this may be a relatively specific abnormality (Teicher et al., 2004). A follow-up study found that PTSD did not appear to affect the growth of the temporal lobe, amygdala, and hippocampal volumes

TABLE 3.3 Structural Neuroimaging Studies of Fetal Alcohol Spectrum Disorders

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Mattson et al. (1996)	4 Males 2 Females (13.0, 8–19)	6 Males 1 Female (12.3, 8–18)	T2/PD 4 mm contiguous slices, manual ROI.	Dec. cerebral vault, basal ganglia, diencephalon; basal ganglia smaller when control for TBV.	Cerebellar vault was smaller but did not reach significance.
Sowell et al. (1996)	3 Females 6 Males (15.1, 8–22)	13 Females 11 Males (14.3, 8–24)	T1 sagittal 5 mm slice thickness, 2.5 mm gap; manual tracing of mid-sagittal section of cerebellum.	Dec. area in anterior ver- mis, not in posterior.	
Swayze et al. (1997)	6 Males 4 Females (15, 4–26)	101 adults, 13 adolescents, 5 children From archive	Iowa and Sioux: 1.5T, T1/T2/PD, 1.5 mm con- tig slices	Microcephaly in 7/10; midline abnormalities 6/10.	Patients with midline brain anomalies had the highest num- ber of craniofacial anomalies.
Archibald et al. (2001)	8 Female FAS 6 Males FAS (11.4 \pm 3.3) 4 Female PEA 8 Male PEA (12.8 \pm 4.8)	20 Female 21 Male (12.8 \pm 4.4)	T1: 1.2 mm contiguous; T2 4 mm contiguous slices; semi-automated segmentation, manual ROI.	FAS global volumes smaller than controls; cerebellum, parietal lobe, caudate more affected; white matter more than gm in cerebrum; hip- pocampus disproportion- ately larger; PEA findings for global vol- ume, caudate and parietal were also smaller but not significant.	Artifact prevented obtaining temporal lobe measures on all participants.
Sowell et al. (2001)	10 Females 10 Males (FAS and PEA, 13.0 \pm 4.0)	12 Females 9 Males (13.5 \pm 5.2)	T1 1.2 mm contiguous slices, shape and area analysis of corpus cal- losum.	Corpus callosum area smaller, posterior region displaced; findings sig in FAS, less severe pattern in PEA.	CC displacement correlates with impairment in verbal learning ability.
Sowell et al. (2001)	11 Females 10 Males (13 \pm 4) alcohol exposed	12 Females 9 Males (13.5 \pm 5)	T1 1.2 mm contiguous slices, whole brain voxel based morphometry.	L hemisphere perisylvian cortices of temporal and parietal lobes—more gray matter, less white matter than controls.	Same population as in Sowell et al. (2001).
Autti-Ramo et al. (2002)	9 Males 8 Females (13)	17 age and gen- der matched	T1 sagittal 1.18 mm contiguous slices, T2 coronal 4 mm 0.8 gap, T2 and FLAIR 5 mm slices 1 mm gap.	Multiple abnormal find- ings in different subjects in cerebrum, cerebellum, corpus callosum; vermis hypoplasia the most con- sistent finding.	Mothers with known alcohol use recruited early in pregnancy; children grouped by trimester(s) during which expe- rienced alcohol exposure; all children with wide sulci also had vermal hypoplasia.
Bookstein, Sampson, Connor, & Streissguth (2002)	60 FAS 60 FAE	30 Male 30 Female (14–37)	T1 SPGR sagittal, develop method of digitizing in set of landmarks.	FAS/FAE have widely varying collection of dysmorphies affecting cc.	Goal to describe morphometric marker for alcohol exposure in individuals without facial stigmata.
Bookstein, Streissguth, Sampson, Connor, & Barr (2002)	30 Males 15 FAS 15 FAE	15 Males subset of group above.	T1 SPGR sagittal, develop method of digitizing in set of landmarks.	Findings similar, more differentiation when incorporate behavioral measures.	Adding neuropsych to landmark measures above.

TABLE 3.3 Continued

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Sowell, Thompson, Matson, et al. (2002)	14 FAS 7 PEA (12.6)	12 Female 9 Male (13.5)	T1 1.2 mm contiguous slices; T2 4 mm con- tiguous coronal; semi- automated volumes, surface based image analysis.	Size and shape abnor- malities in inferior pari- etal/ perisylvian regions bilaterally, dec. brain surface in ventral aspect of frontal lobes.	
Sowell, Thompson, Peterson, et al. (2002)	14 FAS 7 PEA (11 female, 10 male, 13.9)	38 Female 45 Male (13.5)	T1 1.2 mm contiguous slices, semi-automated surface based analysis and gm density.	Sup temporal and inf parietal cortices shifted backward in left hemi- sphere compared to right, less asymmetry than controls in posterior inf temporal lobes (lan- guage areas).	Controls recruited from studies at two different centers.

during a period of 2 years occurring roughly during puberty (DeBellis, Hall, Boring, Frustaci, & Moritz, 2001).

Recently, pituitary volumes were investigated in 61 children with PTSD as a marker of stress-related hormonal differences. No overall differences between cases and controls were found, but a post hoc analysis suggested that the PTSD group may have had larger pituitary volumes after puberty, consistent with hypothesized increased CRH secretion (Thomas & DeBellis, 2004).

An ongoing question has been whether the smaller hippocampal volumes observed in adults were a result of PTSD or a predisposing factor. Gilbertson et al. (2002) addressed this by recruiting identical twins who were discordant for PTSD. They found smaller hippocampi in both affected and nonaffected twins, suggesting that the brain abnormality was a risk factor and not a consequence of PTSD. More recently, a first prospective study of PTSD was performed in adults to determine what abnormalities if any developed during the course of the disorder. Bonne et al. (2001) investigated 37 trauma-exposed individuals, of whom 10 later developed PTSD, obtaining imaging measures both immediately after the trauma and then after a follow-up period of 6 months. They did not find evidence of hippocampal abnormalities at either time point.

The abundance of potential confounding issues makes us question such an interpretation of brain abnormalities as markers of vulnerability or result of trauma difficult to address. The choice of controls may be important, as individuals who have been exposed to trauma but do not develop symptoms may be a better comparison group but are difficult to recruit. Another methodological problem is the high rate of psychiatric comorbidity in patients with PTSD, particularly of depression, which has also been associated

with decreased hippocampal volumes (Jelicic & Merckelbach, 2004).

In summary, the limited studies available of children with PTSD showed different findings from those reported in adults. Furthermore, due to methodological limitations, the temporal sequence between the morphological findings and the onset of symptoms is unclear, both in children and in adults with the disorder. More longitudinal studies in high-risk children are warranted to differentiate whether stress to traumatic experience can affect the developing brain or whether children with subtle brain abnormalities are particularly vulnerable to develop PTSD when exposed to traumatic experiences.

Disorders with Known Genetic or Environmental Etiology: Conclusion

The variety of brain and physical findings associated with these disorders is a graphic example of the complexity of the relationships of gene, environment, and behavior. However, one feature that is clear is that with the exception of more severe cases of FAS, the structural abnormalities associated with these disorders tend to be diffuse and subtle, albeit with some structures being more impacted than others. The availability of increasingly sophisticated voxel-based methods that are able to show differences in areas without needing to specify an a priori region of interest may be able to more effectively map relationships of these types of diffuse structural abnormalities with functional changes. MRI techniques such as DTI able to provide information about microstructural features of affected tissues may also be more informative, although the structural studies serve as an important guide regarding where to begin to look.

One of the challenges and opportunities presented by the study of disorders with known genetic or environmental causative factors is how to explain the range of resulting phenotypes. A major contribution to this is the highly complex determination of any of these behavioral features, such that the presence of other genes will affect how an insult in a specific gene is expressed. Sometimes it may be due to a genetic variation in an aspect of the associated pathway, as seen in the example of animal studies of FAS where teratogenic effects of a given dosage of alcohol were moderated by polymorphism of pertinent enzymes (Cumings, & Kavlock, 2004; Das, Cronk, Martier, Simpson, & McCarver, 2004). In PTSD, there is some evidence to suggest that a smaller hippocampus may represent a risk factor for developing the disorder. Timing of exposures is also important. Alcohol exposure can result in highly different results depending on when in pregnancy it occurs, and exposure to traumatic events may be associated with different physiological and perhaps structural effects depending on whether it occurs during childhood or after.

Another way of describing the variety of responses an individual may have to a given perturbation is in terms of resilience, an understudied area in childhood-onset neuropsychiatric disorders (Charney, 2004; Curtis & Cicchetti, 2003). A generalized attention to how specific environmental features may impact the outcome of disorders with known genetic or environmental causes has been sparse. Data from other psychiatric illnesses, for example, the increased rate of rehospitalization in patients with Schizophrenia residing in families with high levels of expressed emotion, are suggestive that such factors can significantly measure outcome (Kuipers, 1979; Miklowitz, 2004). By determining which features correlate with a better outcome in children who are faced with a particular genetic or environmental insult, it may be possible to identify areas or times of development that would be particularly important to support prospectively in affected children and their families and thus minimize the detrimental effect on the long-term developmental trajectory.

Neuropsychiatric Disorders Commonly First Diagnosed in Childhood

This section summarizes neuroimaging findings in the more common neuropsychiatric disorders typically first seen in childhood. Autistic Disorder is classified as a pervasive developmental disorder which is notable for pronounced deficits in social behavior and communication. Dyslexia is a circumscribed cognitive disorder associated with difficulties in processing written language.

Attention-Deficit/Hyperactivity Disorder is associated with difficulties in attention and impulse control, and Obsessive-Compulsive Disorder, also associated with a specific variety of difficulties in impulse control, has a significant anxiety component.

Autistic Disorder

Autism is characterized by impairments in communication and social interaction and a markedly restricted repertoire of activities and interests (Folstein & Rosen-Sheidley, 2001; Rutter, 2000). It is but one disorder that occurs along a spectrum of conditions commonly described as Autism Spectrum Disorders (ASD). ASD includes high- and low-functioning Autism, Asperger's syndrome, and a subthreshold category, termed Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS), primarily reserved for those individuals who do not meet full criteria for Autism. The onset of Autism is by definition prior to age 3 years. Recent estimates of the prevalence of Autism, strictly defined, are approximately 3 to 4 out of every 10,000 individuals (Yeargin-Allsopp et al., 2003), but this figure rises considerably when including the entire Autism spectrum (Baird et al., 2000; Chakrabarti & Fombonne, 2001). Of those diagnosed with Autism, 75% are male, approximately 70% are classified as mentally retarded, and 15% to 20% of these individuals develop seizures at some point during their lifetime.

Twin and family studies suggest a strong genetic basis for the disorder. Concordance rates for ASD and the broader phenotype (i.e., subclinical expression of the disorder) in monozygotic twins are quite high (approximately 90%), especially when contrasted with the rate among same-sex dizygotic twins (5% to 10%; Bailey et al., 1995). Such a discrepancy indicates a significant genetic loading in the transmission of autistic traits. However, no clearly defined etiology or diagnostic markers have been identified for the vast majority of cases. To date, the most prominent theories to account for the range of symptoms and characteristics present in ASD have been neuropsychological in nature. One theory regarding the basis of Autistic Disorder is that it represents an abnormality in theory of mind, a term used to describe the ability to attribute thoughts, beliefs, and desires to oneself and to others and to understand that others may have thoughts, beliefs, and desires that differ from one's own (Premack, 1978). Baron-Cohen, Leslie, and Frith (1985) first tested theory of mind abilities in individuals with ASD, finding deficits consistent with socialization difficulties observed in ASD individuals' everyday life. Ever since this seminal study, theory of mind research has had a significant and

ever growing impact on the Autism field. Functional neuroimaging studies have consistently demonstrated a network of regions, including medial prefrontal cortex, posterior superior temporal sulcus, and temporal poles, as particularly important for supporting intact theory of mind ability (Frith, 2001). Theory of mind has been particularly successful in accounting for the social difficulties experienced by people with ASD, but the nonsocial aspects of the disorder generally remain unexplained.

Other researchers have described prominent abnormalities in executive functions in Autistic Disorder. Executive functions (EF) are a group of cognitive capacities that enable an individual to complete novel problem-solving tasks that require flexible thinking, future orientation, and the formulation of original strategies. EF has been linked with prefrontal functioning; however, based on functional imaging studies, it is clear that this array of cognitive capacities is subserved by various networks of brain regions, including subcortical structures and the cerebellum in addition to the previously implicated prefrontal regions (Carpenter, Just, & Reichle, 2000; Tamm, Menon, & Reiss, 2002). Potential EF deficits in Autism were investigated after noticing similarities in behavior between patients with frontal lobe injury and those with Autism (Damasio & Maurer, 1978; Rumsey, 1985) and have since been robustly demonstrated in autistic individuals and first-degree family members (Biro & Russell, 2001; Hughes, 1996; Hughes, Leboyer, & Bouvard, 1997; Hughes, Plumet, & Leboyer, 1999; Ozonoff, Strayer, McMahon, & Filloux, 1994).

In her seminal discussion of the characteristic cognitive features of Autism, Frith (1989) described the tendency of individuals with the disorder to favor local over global processing (a reverse of the typical trend) as a “weak drive for central coherence,” which is the third major psychological formulation for Autism. One unusual and appealing aspect of this theoretical account is its ability to explain both strengths and weaknesses in the neuropsychological profile of individuals with ASD. A brain basis for central coherence has only begun to be investigated; Ring et al. (1999) find that when asked to complete an embedded figures task, typically developing individuals are more reliant on prefrontal regions, and ASD individuals are more reliant on primary and association visual areas. In a complementary, well-controlled functional imaging study involving only typically developing adults, there are indications that the local search component of an embedded figures task particularly activates the left superior and inferior parietal cortex (Manjaly et al., 2003).

The following sections, divided by anatomical region, aim to highlight the growing structural imaging findings for individuals with ASD (see Table 3.4). This review is not in-

tended to be comprehensive or encyclopedic; for a detailed recent overview of structural and functional neuroimaging studies involving individuals with ASD, please see Brambilla, Hardan, et al. (2003). Similarly, for a current state of the science on neuropathological studies of ASD, please see Palmen, van Engeland, Hof, and Schmitz (2004).

Total Brain. The study of total brain size in Autism highlights many of the methodological considerations discussed in other sections of this chapter, particularly the importance of well-characterized patient and control groups (e.g., matching on or controlling for IQ), considering differences in image acquisition and analysis, and how the course of brain development (i.e., findings across different age groups and longitudinal findings) may be more informative than its end point.

In Leo Kanner’s (1943) original report of Autism, he points out that 5 of the 11 subjects had notably large heads. Many subsequent studies have supported this initial observation. A postmortem study found increased brain weight in Autism (Bailey et al., 1993), and studies of head circumference (Fombonne, Roge, Claverie, Courty, & Fremolle, 1999; Lainhart et al., 1997; Miles, Hadden, Takahashi, & Hillman, 2000; Stevenson, Schroer, Skinner, Fender, & Simensen, 1997) report that approximately 1 in 5 subjects with Autism meet criteria for macrocephaly (i.e., above the 97th or 98th percentile). Taken together, these findings consistently indicate an elevated rate of macrocephaly among individuals with ASD.

Imaging studies have also been consistent in reporting enlarged brain size in Autism, although the developmental course of this enlargement has been the subject of some controversy. Piven and colleagues (Piven, Arndt, Bailey, & Andreasen, 1996) found that after controlling for IQ, brain size remained enlarged in adolescents and adults with ASD. On the contrary, Courchesne et al. (2001) and Aylward, Minshew, Field, Sparks, and Singh (2002), did not find enlargement in their adolescent and adult samples. Whether the enlargement is static or changes over time has profound implications for informing theories of the pathogenesis in Autism.

In a recent report, Courchesne, Carper, and Akshoomoff (2003) examined cross-sectional imaging and clinical data from 48 children between the ages of 2 and 5 years who were diagnosed as having ASD. Head circumference for the ASD group was smaller at birth compared to healthy controls (body length and birth weight were not statistically different) but underwent a more rapid increase between 1 to 2 months and 6 to 14 months. The accelerated rate of growth slows between ages 2 to 4 years, with the maximum size

TABLE 3.4 Structural Neuroimaging Studies of Autistic Disorder

Study	Patients (Mean Age \pm SD, or Range)	Controls	Method	Findings	Comments
Courchesne, Yeung-Courchesne, Press, Hesselink, & Jernigan (1988)	16 Males 2 Females (20.9, 6–30)	9 Males 3 Females (24.8, 9–37)	Manually traced cerebellar lobules from mid-sagittal MRI scan.	Significantly smaller cerebellar vermal lobules VI and VII.	
Egaas, Courchesne, & Saitoh (1995)	45 Males 6 Females (15.5 \pm 10.0)	45 Males 6 Females (15.5 \pm 9.9)	Manually traced corpus callosal areas.	Smaller corpus callosum, particularly in the posterior sections.	
Piven, Arndt, Bailey, & Andreasen (1996)	26 Males 9 Females (18.4 \pm 4.5)	20 Males 16 Females (20.2 \pm 3.8)	T1 1.5 mm contiguous, semiautomated ROI volumes.	Total brain size enlarged in adolescents and adults with Autism, most in temporal, parietal and occipital lobes.	Findings remained after accounting for height and IQ.
Sears et al. (1999)	26 Males 9 Females (18.4 \pm 4.5)	20 Males 16 Females (20.2 \pm 3.8)	T1 1.5 mm contiguous slices, manual tracing of basal ganglia.	Caudate volume increased, but not putamen or globus pallidus.	Caudate enlargement related to the repetitive and restricted behaviors.
Hardan, Minshew, & Keshavan (2000)	22 Male ADI (22.4 \pm 10.1)	22 Males (22.4 \pm 10.0)	Area of seven subregions of the corpus callosum.	Reductions in anterior sections of the corpus callosum.	Subset reanalyzed controlling for intracranial, total brain, white matter volumes; findings persisted.
Aylward, Minshew, Field, Sparks, & Singh (2002)	58 Males 9 Females (18.8 \pm 10.0)	76 Males 7 Females (18.9 \pm 10.0)	T1 1.5-mm coronal contiguous slices, semiautomated measurement of whole brain volume.	Brain enlargement was observed in autistic children < 12 years and younger but not in older groups, head circumference enlarged in all ages.	Findings suggest abnormal trajectory.
Sparks et al. (2002)	45 ASD 14 DD (26 Males, 3 Females, 3.9 \pm 0.4)	18 Males 8 Females (3.9 \pm 0.5)	Volumes of the cerebrum, cerebellum, amygdala, and hippocampus were measured from three-dimensional coronal MR images.	ASD brain volume larger than DD and controls. Strict Autism subjects had amygdala enlargement greater than expected for cerebral volume.	ASD = Autism Spectrum Disorder; DD = Developmental delay.
Courchesne, Carper, & Akshoomoff (2003)	41 Males 7 Females (2–5)	Head circumference data were compared to two public normative samples	Head circumference, body length, and body weight measurements during the first year were obtained from medical records.	ASD reduced head circumference for the ASD group at birth; rapid increase between 1–2 months and 6–14 months and then slowing.	Abnormal trajectory as potential early marker for Autism.
Barnea-Goraly et al. (2003)	7 Males (14.6 \pm 3.4)	9 Males (13.4 \pm 2.8)	DTI on 3T scanner; 5 mm slices, 1.5 mm gap; 6 directions, b value = 900. FA examined for whole brain using voxel based method.	Reduced fractional anisotropy in white matter areas of the ventromedial prefrontal, ant. cingulate, temporal regions; corpus callosum.	Abnormalities are consistent with regions implicated in social cognitive processes.
Boddaert et al. (2004)	16 Males 5 Females (9.3 \pm 2.2)	7 Males 5 Females (10.8 \pm 2.7)	T1 1.5 mm axial contiguous slices, VBM analysis.	Gray matter concentration red. in bilateral temporal lobes.	

TABLE 3.4 Continued

Study	Patients (Mean Age \pm SD, or Range)	Controls	Method	Findings	Comments
De Fosse et al. (2004)	6 Males with Autism and nor- mal language (8.3 \pm 0.9) 16 Males with Autism and lan- guage impairment (9.8 \pm 2.1)	11 Males with normal language (10.4 \pm 2.7) 9 males with specific lan- guage impair- ment (SLI) (9.9 \pm 2.3)	T1 1.5 mm coronal con- tiguous, semiautomated parcellation into 48 gyral-based divisions per hemisphere.	Reversal of asymmetry in language related regions of frontal cortex seen only in language impaired autistic and control groups.	SLI: specific language impair- ment.
Kates et al. (2004)	14 Male MZ twin pairs 2 Female MZ twin pairs (8.4 \pm 2.6) 7 clinically con- cordant twin pairs, 9 discordant twin pairs	14 Males 2 Females (8.3 \pm 2.4)	T1 1.5 mm coronal con- tiguous slices, semiau- tomated segmentation and parcellation into lobes.	Cerebral gm and wm similar in all twin pairs; cerebellar only similar in concordant twins. Both affected and unaffected twins showed dec. frontal, temporal, occipi- tal wm.	
Lotspeich et al. (2004)	13 LFA males (11.6 \pm 2.1) IQ: NA 18 HFA males (12.1 \pm 3.4) IQ: 94 \pm 17 21 Asperger's syndrome males (12.7 \pm 2.6) IQ: 108 \pm 20	21 Males (12.5 \pm 2.8) IQ: 114 \pm 10	T1 1.5–1.7 mm coronal contiguous slices, semi- automated segmentation and parcellation into lobes.	Inc. gm in LFA and HFA. Nonverbal IQ negatively related to gm in HFA; positively to wm in Asperger's syndrome.	LFA: low functioning Autism, HFA: high functioning Autism. Images acquired on 3 different scanners, one 3T and two 1.5.
Schumann et al. (2004)	19 LFA males 27 HFA males 25 Asperger's syndrome males (7.5–18.5)	27 males (7.5–18.5)	Coronal MRI images were used to trace the amygdala and the hip- pocampus, then outlines of these structures were also checked utilizing axial and sagittal views.	Larger amygdala found only in preadolescent autistic group (ages 7.5–12.5), LFA and HFA had bilaterally inc. hip- pocampal volumes.	

obtained at approximately age 5 years (8 years sooner than that of typically developing children). By adolescence there was no statistically significant difference between the groups. Severity of ASD symptoms correlated negatively with age at onset (earlier onset worse) and positively with the rate and duration of accelerated growth. The authors speculate that continued research may provide a combination of biological and behavioral markers that allow for earlier diagnosis and intervention than are currently common practice.

White and Gray Matter. Among a group of boys with Autism, Herbert et al. (2003) found a trend for cerebral white matter to be disproportionately larger than cortical gray matter and that the hippocampus-amygdaloid complex trended toward being disproportionately smaller. An extension of this study (Herbert et al., 2004), which included subjects with Developmental Language Disorder (DLD), divided white matter into an outer zone and an

inner zone. Only the outer zone, composed of later myelinating axons, was larger in the Autism and DLD groups. The authors suggest that these findings are consistent with an ongoing postnatal process that affects intrahemispheric and corticocortical connections in both Autism and DLD. Other reports of white matter anomalies include a report by Courchesne et al. (2001) of an 18% increase of white matter volume in 2- to 3-year-olds with Autism but a slight decrease in this tissue type for adolescent subjects with Autism.

In examining possible brain-based differences among separate diagnoses within the Autism spectrum, Lotspeich et al. (2004) found that cerebral gray matter is enlarged in both high-functioning and low-functioning boys with Autism relative to controls, and that gray matter volume for individuals with Asperger's syndrome is intermediate between the Autism and control groups (although not

statistically significantly different from either group). Gray matter may therefore covary with severity of ASD symptoms, although replication is needed to confirm these early reports.

Corpus Callosum. The preponderance of reports suggests that corpus callosum size is slightly reduced in Autism. At least four studies indicate that the reductions occur in posterior sections (Egaas, Courchesne, & Saitoh, 1995; Manes et al., 1999; Piven, Bailey, Ranson, & Arndt, 1997; Waiter et al., 2005) of the corpus callosum; another implicates anterior sections (Hardan, Minshew, & Keshavan, 2000). Taken together with the earlier reviewed studies indicating increased brain size in ASD, these findings are consistent with the notion that larger forebrains are associated with relatively smaller corpus callosa (Jancke, Preis, & Steinmetz, 1999; Jancke, Staiger, Schlaug, Huang, & Steinmetz, 1997). Using DTI, Barnea-Goraly et al. (2004) found reduced fractional anisotropy in the genu and splenium of a small group of children and adolescents with Autism. Taken together, these findings may have implications regarding decreased lateralization and interhemispheric connectivity in ASD.

Basal Ganglia. Findings for the basal ganglia are quite variable, including one report of an increase in caudate volume (Sears et al., 1999) in ASD and one report of volumetric differences in and around the basal ganglia in Asperger's syndrome, reflecting bilateral excess of white matter and bilateral reduction of gray matter (McAlonan et al., 2002). In contrast, two other reports (Hardan, Kilpatrick, Keshavan, & Minshew, 2003; Herbert et al., 2003) indicate that group differences in these structures are not statistically significant after controlling for total cerebral volume. Studies of brain-behavior correlates also present findings that are somewhat difficult to interpret. Consistent with the predicted brain-behavior relationship, Sears et al. found that caudate volume correlated positively with the degree of stereotyped repetitive behaviors but not with social or communication deficits in affected individuals. On the other hand, among individuals with ASD, Hardan et al. found no significant relationship between performance on motor tasks (e.g., grip strength and speed in placing grooved pegs in a board) and basal ganglia volume. These findings are not necessarily at odds with one another. The tasks utilized in Hardan et al.'s study may not capture prototypical repetitive behaviors and motor abnormalities commonly observed in ASD (as were assessed by a diagnostic interview in the Sears et al. study); thus, they may rely on a different set of neural systems.

Temporal Lobe Structures. Postmortem studies of ASD brains consistently indicate increased cell packing density and smaller neuronal size in the limbic system (Palmen et al., 2004). Moreover, the amygdala's role in social-emotional behavior and cognition make it an obvious target for ASD imaging studies. Unfortunately, amygdala findings have been contradictory, with reports of increased volume (Abell et al., 1999; Howard et al., 2000), decreased volume (Aylward et al., 1999; Pierce, Muller, Ambrose, Allen, & Courchesne, 2001), and no statistically significant difference in volume (Haznedar et al., 2000).

Sparks et al. (2002) compared 3- to 4-year-old children with Autism, with PDD-NOS, with other developmental disorders, and typically developing children. Amygdala volumes were significantly larger in the Autism and PDD-NOS groups than in the comparison groups. Furthermore, the children with Autism had significantly larger amygdalae than the children in the less severely symptomatic PDD-NOS group.

Superficially contradictory findings may in fact be complementary after taking developmental periods into consideration. In a recently reported cross-sectional study, Schumann et al. (2004) found that the amygdala was indeed larger in preadolescent children with Autism, but among adolescents with Autism, no amygdala volume differences were observed. The pattern of findings among the typically developing controls indicates that amygdala volume continues to increase across these ages, whereas amygdala volume in children with Autism remains stable.

Turning to the hippocampus, smaller hippocampal volumes in ASD have been reported in two studies (Aylward et al., 1999; Saitoh, Karns, & Courchesne, 2001) and larger left hippocampus in one study of both preadolescent and adolescent males (Schumann et al., 2004); however, comparable hippocampal size has been reported in the majority of studies (Haznedar et al., 2000; Howard et al., 2000; Piven, Bailey, Ranson, & Arndt, 1998; Saitoh, Courchesne, Egaas, Lincoln, & Schreibman, 1995).

Consistent with Schumann et al. (2004), one study (Rojas et al., 2004) involving parents of individuals with Autism, adults with ASD, and adults with no familial history of ASD found that both parents of ASD individuals and ASD adults had larger left hippocampi than the comparison group.

Other methodologies have been utilized to examine this brain region, including voxel-based morphometry (VBM). In a VBM study of male adolescents with ASD and matched controls, Waiter et al. (2004) found that individuals with ASD had increased gray matter volume in the right fusiform gyrus, the right temporo-occipital region, the left frontal pole and medial frontal cortex relative to controls.

Similarly, Kwon, Ow, Pedatella, Lotspeich, and Reiss (2004) utilized VBM to assess potential brain-based differences among males diagnosed with high-functioning Autism, those diagnosed with Asperger's syndrome, and a control group of typically developing males. The combined ASD group had decreased gray matter density in the ventromedial regions of the temporal cortex. Also using VBM, Boddaert et al. (2004) showed decreased gray matter concentration in the superior temporal sulcus when comparing children with Autism to typically developing children. And finally, in Abell and colleagues' (1999) study utilizing VBM, individuals with ASD showed decreased gray matter volume in the right paracingulate sulcus and the left occipito-temporal cortex. The localization of these convergent findings is consistent with expectations based on previous social cognitive and functional imaging studies.

Cerebellum. The cerebellum has been the most active area of investigation in Autism structural neuroimaging research. After indications of cerebellar abnormalities from a neuropathological investigation (Bauman & Kemper, 1985), an initial case study demonstrated incomplete development of vermal lobules VI and VII in a young man with Autism (Courchesne, Hesselink, Jernigan, & Yeung-Courchesne, 1987). This was followed by a study indicating a 19% reduction in these lobules for individuals with Autism when compared to controls (Courchesne et al., 1988). A report on a subsample of these subjects indicated more widespread involvement of the cerebellum, with a 12% reduction in cerebellar volume (Murakami, Courchesne, Press, Yeung-Courchesne, & Hesselink, 1989). In a more recent report of the sample enlarged to 50 patients and 53 controls, mean sizes of vermal lobules VI and VII were not different. However, in contrast to the Gaussian distribution of values in the control group, the values in the autistic group were bimodally distributed. Based on this distribution, two distinct subgroups were proposed, one of 86% of the patients having a mean midsagittal area of vermal lobules VI and VII 16% smaller than the control group, and the other of 12% of the patients having a 34% larger mean area.

In contrast to these studies, a number of investigators have not found differences in the midsagittal area of vermal lobules VI and VII in Autism (Hashimoto et al., 1993; Holttum, Minshew, Sanders, & Phillips, 1992; Piven, Saliba, Bailey, & Arndt, 1997). The importance of controlling for IQ in ASD neuroimaging studies was exemplified by a study of 15 high-functioning males with Autism who had smaller vermal lobules VI and VII when compared to a group of individuals matched for age and parental

socioeconomic status, but not when compared to a group matched for nonverbal IQ (Piven et al., 1992).

Although cerebellar MRI findings in Autism remain controversial, accumulating evidence of the cerebellum's role in learning and cognition (Allen, Buxton, Wong, & Courchesne, 1997) and its extensive connections to the rest of the brain make for an intriguing hypothesis in the pathogenesis of Autism. Moreover, newer studies, using refined methodologies, have noted more fine-grained differences in cerebellar volume, for example, reduced white matter volume of the cerebellum in people with ASD as compared to controls (McAlonan et al., 2005) and bilaterally increased gray matter (Abell et al., 1999).

Intriguingly, Kates and colleagues (2004) found that when they examined neuroanatomic variation among monozygotic twin pairs discordant for the narrow phenotype of Autism, cerebral structures, regardless of tissue type, exhibited high intra-class correlations, whereas the cerebellar region did not. These findings may indicate that the cerebellum, unlike cerebral structures, is vulnerable to environmental insult. The potential for relatively strong environmental influences on cerebellar development is consistent with its preferential susceptibility to insults such as alcohol, lead, and anoxia and its role in modulating responses to environmental stimuli.

Other Brain Structures/Regions. In addition to the hippocampus and amygdala, one other subcortical structure of potential interest is the thalamus. Given its vast reciprocal connections to practically every other brain region, it likely plays an integral role in functional connectivity and networking vital to many forms and levels of information processing. Tsatsanis and colleagues (2003) showed reduced thalamic volume in ASD relative to matched controls, but only after adjusting for mean differences in total brain volume. Moreover, the relationship between thalamic volume and total brain volume was different for each of these groups; they were strongly correlated in the control group, whereas the correlation in the ASD group did not reach significance. These findings may reflect reduced connectivity between cortical and subcortical structures in ASD and may contribute to the various information-processing difficulties commonly observed in ASD.

Most studies have not found significant differences in ventricle size. One study indicates enlarged lateral ventricles in Autism (Piven et al., 1995), but two other studies find no statistical difference (Creasey et al., 1986; Hardan, Minshew, Mallikarjunn, & Keshavan, 2001). Fourth ventricle enlargement has been reported (Gaffney, Kuperman, Tsai, Minchin, & Hassanein, 1987), but most studies that

have examined it have not found differences (Garber & Ritvo, 1992; Garber et al., 1989; Kleiman, Neff, & Rosman, 1992; Piven et al., 1992).

In a qualitative MRI study of 13 high-functioning adult men with Autism five were noted to have polymicrogyria, one had macrogyria, and one had both macrogyria and schizencephaly (Piven et al., 1990). Similar cortical findings of poly- and microgyria were reported for two patients with Asperger's syndrome (Berthier, Starkstein, & Leiguarda, 1990). These anomalies most likely reflect problems in neural migration during the first 6 months of pregnancy, which may indicate a particularly vulnerable time for external factors such as infections to contribute to the pathogenesis of ASD. Other reports of cortical abnormalities include decreased parietal lobe volumes, manifest by sulcal widening, which was found in 9 of 21 autistic subjects versus none in 12 controls (Courchesne, Press, & Yeung-Courchesne, 1993); gray matter heterotopia (Gaffney & Tsai, 1987); and altered asymmetries of frontal lobe volumes (Hashimoto et al., 1989), particularly for the language association cortex (Herbert et al., 2002; De Fossé et al., 2004).

Summary. The most consistent structural abnormality in MRI studies of Autism is enlarged total brain size, although there are conflicting reports as to whether the increased size persists into adolescence/adulthood. Possibly related are findings of reduced corpus callosum size in ASD. Consistent with neuropathological studies, there is a trend toward finding abnormalities in the amygdala, hippocampus, and cerebellum. The general inconsistency in findings and lack of replicability may be due to varying methodologies, sampling procedures, and so on, and these potential confounds significantly complicate interpretation of results. Although caution is warranted, these findings are generally consistent with observed behavioral findings and the most prominent neuropsychological theories of ASD. Enlarged brains and smaller corpus callosa, for example, may be consistent with an inefficient cognitive processing style as described in the weak central coherence account. Moreover, prefrontal cortex, cerebellar, and subcortical abnormalities are consistent with the oft-reported executive dysfunction in ASD. Finally, abnormalities in the medial frontal, amygdala, and temporal regions fit with the social cognitive and emotional processing difficulties predicted by the theory of mind account. Mapping the developmental course of these brain-based abnormalities and their relationship to symptom presentation and neuropsychological impairments may help to elucidate theoretical accounts and isolate neural substrates of autistic behavior.

Dyslexia

Although there are various definitions for dyslexia, the essence of the disorder was captured nicely by this 1896 report by W. Pringle Morgan in the *British Medical Journal*: “Percy F. . . . aged 14, . . . has always been a bright and intelligent boy, quick at games, and in no way inferior to others of his age. His great difficulty has been—and is now—his inability to learn to read” (Pringle, 1896).

This straightforward concept of difficulty learning to read despite intelligence, motivation, and education belies the complexity of the many distributed systems within the central nervous system necessary to achieve a complex cognitive task such as reading. The challenge is to discern the pertinent neural circuitry subcomponents that are amenable to investigation. In this regard, studies of dyslexia are farther along than studies of most other pediatric neuropsychiatric disorders in that two distinct but interacting pathways have been well delineated and investigated. These two pathways are the orthographic, involved in the visual interpretation of symbols, and the phonologic, involved in the auditory-processing aspects.

A given person may have anomalies of none, one, or both of these pathways, and studies not accounting for different subtypes may risk “apples to oranges” comparisons, obscuring neuroanatomical differences. IQ also seems to be a parameter particularly important in dyslexia studies (Leonard et al., 2002). For instance, the literature for dyslexia subjects with high IQ tends to report large and asymmetrical brain structures, whereas the literature for dyslexia subjects with low IQ tends to report small and symmetrical brain structures.

Temporal Lobe. Most dyslexia imaging studies have focused on the planum temporale, a part of the superior temporal gyrus. Interest in this region was spawned by a seminal postmortem study of 100 brains that found a left-greater-than-right asymmetry of the planum temporale (Geschwind & Levitsky, 1968). This asymmetry was thought to be related to the left hemisphere's more prominent role in language, which has been well documented from studies of people with unilateral strokes and other lesion studies. Dyslexia then was hypothesized to be related to an alteration of this normal asymmetry, and several early postmortem (Galaburda, 1995) and MRI studies (Hynd & Semrud-Clikeman, 1989; Larsen, Odegaard, Grude, & Høien, 1989) supported this. However, subsequent larger studies have not found a link between dyslexia and loss of planum temporale asymmetry (Best & Demb, 1999; Eckert

et al., 2003; Heiervang et al., 2000; Leonard et al., 1993; Leonard et al., 2001; Preis, Engelbrecht, Huang, & Steinmetz, 1998; Robichon, Levrier, Farnarier, & Habib, 2000; Rumsey et al., 1997; R. T. Schultz et al., 1994).

Relatedly, Heschl's gyrus, the primary auditory cortex, where audio input to the brain is first processed (Morosan et al., 2001), has been related to language impairment but has not been consistently demonstrated to be anomalous in dyslexia (Leonard et al., 2002).

Parietal Lobe. Because of its functional connectivity to the temporal lobe, the parietal lobe has also been of interest in studies of dyslexia. Passive listening first activates the superior temporal gyrus and then the inferior parietal lobe (Friston, Harrison, & Penny, 2003), where the phonological inputs are mapped to orthographic symbols (Y. Chen, Fu, Iversen, Smith, & Matthews, 2002).

Here again the literature is somewhat difficult to reconcile. Three studies of high-functioning adults with dyslexia have found larger parietal areas caudal to the infra-Sylvian fissure in the dyslexia group (R. L. Green et al., 1999); exaggerated left-greater-than-right asymmetry of the planum parietale (the ascending branch of the Sylvian fissure; Leonard et al., 2001), and, in a group of dyslexic engineering students, an exaggerated left-greater-than-right asymmetry of the peri-Sylvian region that predicted nonword dictation performance (Robichon et al., 2000). However, in a study of dyslexic children with normal verbal IQ but multiple reading skill deficits, abnormal parietal asymmetries were found (Eckert et al., 2003).

Frontal Lobe. The frontal lobe receives input from the temporal and parietal and, among other things, processes phonologic information to prepare for speech output (Gelfand & Bookheimer, 2003). Structural MRI studies of the frontal lobe in its entirety have not yielded consistent findings; however, in studies that specifically address a part of the frontal lobe, the inferior frontal gyrus, a consensus is emerging. A study of dyslexic adults found a right-greater-than-left asymmetry of the inferior frontal gyrus in the dyslexia group (Robichon et al., 2000); a voxel-based morphometry study, also of adults, found decreased left inferior frontal gyrus gray matter volume in the dyslexia group (Brown et al., 2001); and surface area measurements of the pars triangularis (the middle of the three inferior frontal gyri) were smaller in dyslexia (Eckert et al., 2003).

Cerebellum. Functional MRI studies have implicated the cerebellum in a variety of reading and phonological

tasks (Brunswick, McCrory, Price, Frith, & Frith, 1999). The cerebellum has robust reciprocal anatomical connections to the frontal, temporal, and parietal regions previously discussed.

One structural MRI study of dyslexic adults found right-greater-than-left asymmetry of cerebellar gray matter volume in their control but not dyslexic group (Rae et al., 2002), and another found less gray matter in left and right semilunar lobule, a part of the posterior cerebellar lobe (Brown et al., 2001). A voxel-based morphometry study of dyslexic children reported less gray matter in the semilunar lobule, but only on the left (Eckert et al., 2003).

Asymmetry. The issue of asymmetry, or more specifically, lack of typical asymmetry, is more prominently represented in the literature on dyslexia than in other disorders examined. To address interhemispheric asymmetry in a group of 16 dyslexic men age 18 to 40 years and 14 controls matched for sex, age, educational level, handedness, socioeconomic background, and general intelligence (Casanova et al., 2004), we coregistered a brain image with its left/right mirror image and examined the deformation needed to achieve alignment. From this a color-coded map of asymmetries was created, indicating a large area of asymmetry in the medial temporal lobe (a reversal of the typical left-greater-than-right in this region), but also smaller areas of asymmetry in six other regions encompassing both limbic and extrapyramidal systems. Consistent with the studies mentioned earlier, the planum temporale was not one of the areas differing in symmetry.

Summary. For many of the pediatric-onset neuropsychiatric disorders, structural MRI anomalies have been reported for a variety of anatomically connected structures covering most general regions of the brain. This widely distributed collection of structural abnormalities suggests that studies of connectivity, such as those using DTI, may be particularly useful in dyslexia. A DTI study of dyslexic adults found white matter anomalies in the temporal-parietal region (Klingberg, Hedehus, et al., 2000). Future studies will need to continue the trend toward greater anatomical specificity and attempt to link the underlying neuroanatomic anomalies, not to dyslexia per se, but to the cognitive subcomponents of reading and language processing that come together to meet criteria for the diagnosis.

Attention-Deficit/Hyperactivity Disorder

ADHD is a clinically heterogeneous disorder with key clinical symptoms including persistent difficulty with

attention, impulsivity, and hyperactivity. It is estimated to affect between 3% to 10% of children. Reports of the ratio of affected males to females have ranged from 4:1 to 9:1, with a higher male: female ratio in clinics than in community settings (American Psychiatric Association, Task Force on *DSM-IV*, 2000; Barbaresi et al., 2004; Dey & Bloom, 2005). Although many children diagnosed with the disorder show clinical improvement with maturation, approximately 30% of individuals will continue to meet criteria for the disorder in adulthood (Kessler et al., 2005).

ADHD was first described over 100 years ago (Still, 1902) as a disorder of hyperactivity mostly affecting boys. Despite its long history and high incidence its etiology and pathophysiology are not yet well understood. It has been shown to have a strong genetic component in both twin and adoption studies, with an estimated heritability of .76 obtained from multiple studies worldwide (Faraone et al., 2005). Several potential disease-susceptibility genes have been identified, including genes associated with dopamine and serotonin transmission. However, at present there is not evidence for any single gene with a strong effect.

Multiple lines of evidence from studies using structural imaging, functional imaging, and neuropsychological testing have supported the role of an abnormality in the frontostriatal regions as underlying ADHD symptoms. In this section we will review the structural neuroimaging literature, which over the past 30 years has yielded a vast amount of data on the structural anomalies associated with the disorder (see Table 3.5). We integrate some central findings in models of the pathogenesis of the disorder, focusing on recent findings. Other reviews of the literature can be found in Giedd, Blumenthal, Molloy, and Castellanos (2001) and Durston et al. (2004).

Structural Neuroimaging of ADHD. The total brain size in ADHD is approximately 5% smaller than in age- and sex-matched controls (Castellanos et al., 1996). Generally, analyses of regional brain abnormalities should control statistically for differences among individuals in total brain volume, preferably by using analyses of covariance rather than simple ratios or proportions (Arndt et al., 1991). There are some possible exceptions, such as when entire compartments of the brain are being assessed (such as the total gray matter). In such cases, there are high correlations of total brain volume with the measures of interest, which can violate some of the assumptions underlying covariate analyses. Additionally, it can be argued that in neurodevelopmental disorders that are likely to have distributed deficits in multiple regions of the brain, covarying for total brain volume could obscure some potentially sig-

nificant differences (Pfefferbaum, Lim, Rosenbloom, & Zipursky, 1990).

Most efforts to localize the brain differences between children with ADHD and children who are typically developing have focused on the frontal lobe, specifically the prefrontal cortex. This reflects some of the current hypotheses of the neurocognitive deficits that underpin the disorder. Different forms of failure of inhibition have been held to be a central deficit in ADHD, and these are linked with specific regions of the prefrontal cortex. For example, tasks such as the stop signal task (in which subjects must respond to a go signal but inhibit a response when presented with a stop signal) have been associated with activation of the right inferior frontal gyrus (Aron, Dowson, Sahakian, & Robbins, 2003; Aron, Fletcher, Bullmore, Sahakian, & Robbins, 2003). Other aspects of response inhibition, as assessed by the classic Stroop task, are supported by the anterior cingulate gyrus, and activation in subjects with ADHD is abnormal in this region (Bush et al., 1999). Others have argued for a central role of impairments in working memory in ADHD, a function typically linked with more dorsolateral regions of the prefrontal cortex (Barkley, 1997; Klingberg, Forssberg, & Westerberg, 2002).

Castellanos et al. (2002) detailed changes over time in the brain of 152 children with ADHD in the largest longitudinal study to date (see Figure 3.8 on p. 160). Children were scanned repeatedly over a 10-year period. The majority of subjects were scanned at least twice, and the trajectories of the development of the gray and white matter, the basal ganglia, and cerebellum were modeled and compared with a comparison group of age- and sex-matched typically developing children. This study examined changes at the level of entire lobes and reported overall reduction in both gray and white matter in the frontal cortex, which appeared to be fixed and nonprogressive. Notably, the reduction of volume in the frontal lobes was modest (approximately a 4% reduction compared to healthy children) and was of a similar magnitude to the reduction found in the other major lobes. In a study that compared 30 children with ADHD with their healthy siblings and healthy unrelated controls, Durston and colleagues (2004) found significant reduction in the left prefrontal gray and left prefrontal white matter in affected children and, of particular importance, a similar significant reduction in the right prefrontal gray matter in unaffected siblings relative to unrelated healthy controls. It is noteworthy that significant and near-significant volume reductions were also found in the left occipital and parietal lobes in the affected probands alone.

These findings of volume loss in several lobes might seem to run counter to the postulation of specific frontostriatal

TABLE 3.5 Structural Neuroimaging Studies of Attention Deficit and Hyperactivity Disorder

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Hynd et al. (1993)	8 Males 3 Females (11.08 \pm 2.52)	6 Males 5 Females (11.03 \pm 2.77)	“Best” axial slice from MRI scan measured.	L caudate wider than R in normal subjects, reversed in ADHD.	High variability in measurements.
Giedd et al. (1994)	18 Males (11.9 \pm 2.5)	18 Males (10.5 \pm 2.3)	Midsagittal cross-sectional area of the corpus callosum, divided into seven sections, was measured from MRI scans.	Rostrum and rostral body of corpus callosum smaller in ADHD.	Rostral body correlated significantly with hyperactivity ratings.
Aylward et al. (1996)	10 Males (11.26 \pm 1.62)	11 Males (10.71 \pm 1.98)	Manual ROI volumes of caudate, putamen, and globus pallidus, corrected for brain volume.	Globus pallidus smaller in ADHD (significant on left).	
Castellanos et al. (1996)	57 Males (11.65 \pm 2.97)	55 Males (12.03 \pm 3.06)	Manual ROI volumes.	Total cerebral volume, caudate, globus pallidus smaller in ADHD.	Supports right prefrontal-striatal-cortical circuitry dysfunction in ADHD.
Filipek et al. (1997)	15 Males (12.4 \pm 3.4)	15 Males (14.4 \pm 3.4)	Manual ROI volumes.	R and L caudates and R anterior superior white matter smaller in ADHD, posterior white matter volumes decreased only in stimulant non-responders.	First study to quantify gray and white matter separately.
Mataro, Garcia-Sanchez, Junque, Estevez-Gonzalez, & Pujol (1997)	8 Males 3 Females (14.6 \pm 0.5) IQ: 101.5 \pm 8.5	16 Males 3 Females (14.8 \pm 0.7) IQ: 109.4 \pm 7.7	Single-slice transversal measurements of the head of the caudate nucleus.	Larger right caudate.	
Castellanos et al. (2001)	50 Females (9.7 \pm 2.6)	50 Females (10.0 \pm 2.5)	Manual ROI volumes.	Decreased volume in cerebellar lobules VIII to X.	
Overmeyer et al. (2001)	15 Males 3 Females ICD-10 hyperkinetic disorder (10.4 \pm 1.7)	15 Males 1 Female (10.3 \pm 1.2)	Voxel based morphology.	Grey matter deficits in the R superior frontal gyrus and R posterior cingulate cortex.	Subjects also met criteria for ADHD.
Castellanos et al. (2002)	63 Females (9.4 \pm 2.6) 89 Males (10.5 \pm 3.1)	56 Females (10.0 \pm 2.6) 83 Males (10.9 \pm 3.5)	Automated ROI lobar volumes. Subjects were scanned repeatedly over a 10-year period.	Dec. volumes in cerebellum, prefrontal cortex; initially smaller caudate “normalized.”	Subjects scanned repeatedly over 10-year period. The largest study of its kind. There was a correlation between all clinical measures of severity and volume loss.
Mostofsky, Cooper, Kates, Denckla, & Kaufmann (2002)	12 Males (10.1, 8.1–13.8) FSIQ: 115, 101–131	12 Males (10.2, 8.3–13.6) FSIQ: 125, 112–136	Talairach based grid to estimate lobar and sublobar volumes.	Widespread volume reduction in the prefrontal cortex.	The volume loss also affected the premotor cortex. A later study used similar methods to demonstrate volume decreases in the left deep white matter of boys with Tourette’s syndrome Kates et al. (2002).
Castellanos et al. (2003)	Compared monozygotic twins, discordant for ADHD 8 Pairs of males 1 Pair of females (11.0 \pm 3.2)		Automated volumetric measures of grey and white matter, basal ganglia and cerebellum.	Twin with ADHD had a significantly smaller caudate than the unaffected twin.

TABLE 3.5 Continued

Study	Patients (Mean Age \pm SD, or Range)	Controls	Method	Findings	Comments
Hill et al. (2003)	17 Males 6 Females (9.35 \pm 1.82)	16 Males 8 Females (9.36 \pm 1.64)	Manual ROI volumes.	Reduction in volume of R superior prefrontal lobes. No group differences in basal ganglia. Decreased volume of cerebellar lobules 1 to V and VIII to X.	The volume reduction was associated with better performance in a test of sustained attention.
Sowell et al. (2003)	11 Females (11.6 \pm 2.8) 16 Males (12.8 \pm 3.2) FSIQ: 109 \pm 18	17 Females (11.8 \pm 3.1) 29 Males (12.2 \pm 3.3) FSIQ: 114 \pm 13	Surface based computational image analysis, mapping regional changes in cortical morphology and grey matter density.	Reductions in DLPFC, temporal cortex, parietal cortex; GM density increased in post. temporal and inf. parietal lobes.	
Durston et al. (2004)	30 Males (12.1 \pm 2.5)	30 unaffected male siblings (11.6 \pm 3.2) 30 Healthy male controls (10.7 \pm 1.9)	Automated measures of grey and white matter of major lobes and cerebellum.	Smaller frontal gm, R cerebellum in ADHD.	Some volume losses also seen in unaffected siblings compared to healthy controls.

pathology in ADHD, but as the level of analysis was the entire lobe, more subregional changes affecting only a small proportion of the total lobe may have been missed. In this vein, it is interesting that more recent developments, which have allowed such regional specificity, have reported volume changes in the prefrontal cortex in areas where cortical loss would be expected on the basis of neurocognitive models. For example, using a surface-based analytic technique that

allows mapping of the entire cortex at the level of individual voxels, Sowell and colleagues (2003) reported focal abnormal cortical morphology in portions of the dorsolateral prefrontal cortex. In a group of 27 children with ADHD (compared with 47 healthy controls), they found that the brain surface extent (reflected by a decreased distance from the center of the brain) appeared to be reduced by up to 4 mm bilaterally in the inferior dorsolateral prefrontal cortex.

Figure 3.8 Predicted unadjusted longitudinal growth curves for total cerebral volumes for patients with ADHD and controls. *Source:* From “Developmental Trajectories of Brain Volume Abnormalities in Children and Adolescents with Attention-Deficit/Hyperactivity Disorder,” by F. X. Castellanos et al., 2002, *Journal of the American Medical Association*, 288(14), pp. 1740–1748.

By contrast, there was a trend for increase in the brain surface extent in more dorsal frontal regions. Although this study is limited by its relatively small sample size and cross-sectional nature, it is an elegant demonstration of the potential of techniques that map cortical changes at the level of individual voxels.

Overmeyer and colleagues (2001) used a different voxel-based method of estimating volume change and reported specific hits to subregions such as the right superior frontal gyrus and the posterior cingulate cortex (Overmeyer et al., 2001). Yet another approach is to use standard templates to define regions of interest, such as Talaraich-based stereotaxic grid. Mostofsky and colleagues (Mostofsky et al., 2002) adapted such as grid for pediatric brains and reported a reduction in the prefrontal and premotor gray and white matter in 12 boys with ADHD.

These automated and semiautomated techniques complement the findings of increasingly precise volumetric studies that trace regions of interest manually. Many of these earlier studies are detailed in Table 3.1 and have been discussed in Giedd et al. (2001). Recent key volumetric studies have detected smaller right-sided prefrontal brain regions measured en bloc (Castellanos et al., 1996; Filipek et al., 1997) in boys with ADHD that were correlated with neuropsychological performance on tasks that required response inhibition (Casey et al., 1997). In the first study to differentiate the gray and white matter, right anterior white matter was also reduced in ADHD boys (Filipek et al., 1997). However, this difference must be interpreted with caution as the patient group was 2 years younger on average than the controls ($p = .12$, $n = 15$ per group) and because white matter volume increases linearly with age in this age range (Paus et al., 1999; Reiss et al., 1996). The finding was replicated by another group on a larger sample of 26 children with ADHD, which found a volume loss in the right, but not left, superior prefrontal region (Hall, Dhillia, Charalambous, Gogos, & Karayiorgou, 2003). In one of the very few studies on adults with ADHD, Hesslinger and colleagues (2002) reported a significant reduction in the volume of the left orbitofrontal cortex in eight unmedicated male patients. In brief, there are consistent findings of volume reduction in the prefrontal lobe, with rapid advances in defining more precisely the exact regions which are compromised in ADHD.

The prefrontal cortex is richly interconnected with the basal ganglia in a series of parallel loops that are thought to support mechanisms of attention and motor control (Alexander, DeLong, & Strick, 1986). It has been proposed

that ADHD results from dysfunction in such frontostriatal circuitry. Castellanos (2002) and others have argued that structural and neurochemical (primarily dopaminergic) anomalies may contribute to abnormal reward mechanisms in ADHD. These result in a marked intolerance to delay and preference for immediate gratification, even when this is not an optimal behavioral strategy (Sonuga-Barke, Dalen, & Remington, 2003). This theory would predict structural anomalies in the basal ganglia to parallel the changes in the frontal cortex in ADHD already discussed. A reduction or marked asymmetry in the volume of the body and/or head of the caudate nucleus has been reported by several groups (Castellanos et al., 1994, 1996, 2001, 2003; Hynd et al., 1993; Mataro, Garcia-Sanchez, Junque, Estevez-Gonzalez, & Pujol, 1997), although there is no consensus on which caudate is affected, and there are several negative findings (Bussing, Grudnik, Mason, Wasiaak, & Leonard, 2002; Filipek et al., 1997; Hill et al., 2003). In the Castellanos et al. (2002) longitudinal study, the caudate emerged as the only structure showing a developmental trajectory that was not completely parallel to the healthy comparison group. Rather, over time the smaller caudate tended to normalize in size, a significant finding that will be discussed later. The inconsistencies in the many studies that measure the caudate are likely to reflect differences in methodology, such as the orientation of the slices used for definition and defining anatomical landmarks. For example, the mean coefficient of variation in the two studies that used single slice area measures of the caudate (Hynd et al., 1993; Mataro et al., 1997) was 0.22 ($SD = 0.04$), which is significantly greater than the coefficient of variation in the studies that reported volumes (Castellanos et al., 1996; Mataro et al., 1997; mean = 0.14, $SD = 0.03$, $t = 3.20$, $df = 6$, $p = .02$).

Neither of the anatomic MRI studies that reported putamen volumes detected significant diagnostic group differences (Aylward, Reiss, et al., 1996; Castellanos et al., 1996), although statistical power was insufficient in one study to rule out type II error (Aylward, Reiss, et al., 1996).

The output nuclei of the basal ganglia are the internal segment of the globus pallidus and the substantia nigra pars reticulata, but the volume of the latter cannot generally be measured with MRI, and the size of the globus pallidus can only be measured as a unit (lateral and medial segments together), and then only with difficulty. Still, this region has been found to be significantly reduced in size in ADHD (Aylward, Reiss, et al., 1996; Castellanos et al., 1996), although these two studies differed in finding the larger difference on the left and right sides, respectively.

Although total corpus callosum area has not differed from controls in any study, smaller anterior regions have generally been found in ADHD subjects (Giedd et al., 1994; Hynd et al., 1991). The largest MRI study did not confirm these differences when measurements were obtained from images that did not control for the positioning of the brain (Castellanos et al., 1996). The rostrum is the most anterior (and inferior) portion of the corpus callosum, and nearly all findings in ADHD have been anterior. The one exception was based on 15 ADHD subjects that included 5 stimulant nonresponders. The authors found that the subgroup of stimulant nonresponders had the smallest splenium area (Filipek et al., 1997). Examination of their data shows that their finding of a difference in the posterior corpus callosum would not have reached significance without the inclusion of those 5 subjects. Given the known heterogeneity and comorbidity of ADHD, we can speculate that posterior brain changes may be associated with ADHD symptoms secondary to a learning disability, which would explain the absence of benefits from stimulant treatment.

Several influential models of attention have emphasized the distributed nature of the neural systems that mediate attention. Posner and Rothbart (1998), for example, argues that the right parietal cortex plays an important role in establishing and maintaining a vigilant state and in orienting to stimuli. Volumetric deficits in both white and gray matter in the parietal lobes have been reported, complemented by a demonstration of loss of cortical density in the region (Castellanos et al., 2002; Sowell et al., 2003), although there are some negative findings (Durstun et al., 2004). Automated methods that allow examination of the entire brain have also demonstrated volume losses in the cortical and occipital lobes (Castellanos et al., 2002; Durston et al., 2004). A study that defined the most severely affected regions within these lobes suggests that the changes are prominent in heteromodal cortical areas—the anterior and midtemporal cortex and inferior parietal cortex—which integrate sensorimotor percepts and allow these to guide attention (Sowell et al., 2003).

A reduction in the volume of the cerebellum is one of the most consistent findings in ADHD. Reduction in the inferior posterior, but not superior posterior, lobule is the prominent regional finding. These morphological abnormalities have been linked with two aspects of ADHD. First, poor coordination is a frequent finding in children with ADHD, and the cerebellum is important in fine motor control (Rasmussen & Gillberg, 2000). Second, many children with ADHD have deficits in time perception, being unable, for example, to estimate time intervals accurately (Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001).

This may contribute to the sluggish cognitive tempo thought to characterize the high variability in performance and frequent lapses in concentration so characteristic of ADHD. Cerebrocerebellar circuits have been described which convey information from the cortex via the pons to cerebellum, which projects back to the cortex via the thalamus. Such circuits are important in determining temporal relationships and possibly in the timing of fine motor actions (Ivry, Spencer, Zelaznik, & Diedrichsen, 2002; Rubia, Noorloos, Smith, Gunning, & Sergeant, 2003).

Neuroimaging of ADHD is beginning to examine subtle structural anomalies of white matter. Several studies have reported reductions in total white matter volume in several lobes (Castellanos et al., 2002; Durston et al., 2004; Overmeyer et al., 2001). There is considerable interest in applying DTI techniques to characterize white matter changes at a more meaningful physiological level and to delineate possible white matter tract differences between children with ADHD and healthy children.

One of the most striking features of ADHD is its tendency to improve with age in a majority of cases. Little is known of the neurobiology shaping this natural history. In the only longitudinal structural study, Castellanos and colleagues (2002) reported deficits in the gray and white matter and cerebellum that did not progress over time. The only exception to the fixed, nonprogressive deficits was in the caudate nucleus, which appeared to normalize in volume in late adolescence, possibly mediating much of the clinical improvement in the syndrome. Future studies could usefully exploit the difference in outcome in children with ADHD to define structural characteristics associated with different levels of improvement.

Few studies have attempted to delineate the relative influence of genotype and environmental factors in determining the neural substrate of ADHD. One approach is to examine monozygotic (MZ) twins who are discordant for the disorder; as the twins are genetically identical, differences between them may highlight those structural differences most susceptible to environmental influences in the pathogenesis of ADHD. Castellanos and colleagues (2003) recruited nine such pairs of MZ twins discordant for ADHD and found that the only structural differences lay in a reduction in the volume of the caudate. This suggests that the caudate may be particularly susceptible to factors such as birth complications (specifically, breech presentation), which were more common in affected twins.

Most of the structural studies in ADHD have been limited by small sample size, their cross-sectional nature, and the possible confounding effects of comorbidity and mediation effects. Despite the methodological limitations,

a picture begins to emerge of consistent, if complex, interconnected structural anomalies in ADHD, which fit reasonably well with some of the neurocognitive models of the disorder. At the cortical level, there is evidence for distributed subtle anomalies that may hit the regions most implicated by other modalities (such as functional imaging and lesion studies) in the mediation of attention. Particularly good evidence emerges for the involvement of the prefrontal cortices and right parietal cortex. The prefrontal cortical areas project to basal ganglia, which also demonstrate structural alterations, most convincingly found in the caudate nucleus. Thus, both components of the corticostriatal loops that mediate attention show structural change.

Obsessive-Compulsive Disorder

A similar theme of interaction between the frontal cortex and basal ganglia emerges in the pathogenesis of Obsessive-Compulsive Disorder (OCD). OCD is a common neuropsychiatric disorder characterized by repetitive, intrusive thoughts and ritualistic behaviors. It affects between 2% and 3% of the population and appears to have a bimodal incidence with one peak in childhood—perhaps as many as 80% of cases having a childhood onset—and another in adulthood (Geller et al., 2001; Swedo, Leonard, & Rapoport, 1992). There are some differences between the childhood- and adult-onset forms of the disorder: Childhood-onset OCD has a stronger familial loading, greater male preponderance, and higher incidence of tics and Tourette's syndrome (Geller et al., 1998). However, the similarities outweigh the differences, and study of the childhood form of the disorder can be particularly illuminating as confounds such as chronic symptoms and exposure to multiple medications are less prominent.

Most theorists hold that OCD is the result of imbalance in the corticostriatal-thalamic circuitry (Modell, Mountz, Curtis, & Greden, 1989; Rapoport, 1990). Specifically, the basal ganglia fail to provide sensory gating by filtering and suppressing input from frontal cortical regions. Thus, a “hyperactive” orbitofrontal cortex and anterior cingulate gyrus send outputs to the caudate and nucleus accumbens, which in turn inhibit the globus pallidus, halting its tonic discharge to the thalamus. The cessation of pallidal inhibitory activity releases the thalamus, and the thalamus feeds this excessive activity forward to frontal cortical regions, completing the cycle.

Much of the support for this model comes from functional neuroimaging studies beyond the scope of this chapter, but which have been reviewed elsewhere (Saxena, Bota, & Brody, 2001). In brief, this work has consistently

demonstrated resting hypermetabolism in the orbitofrontal cortex, cingulate gyrus, and caudate in patients with OCD. In an elegant demonstration of the specificity of this hypermetabolism, several PET studies have demonstrated a partial normalization of increased orbitofrontal and caudate hypermetabolism following effective treatment (Saxena et al., 1999). During provocation of symptoms in OCD, functional imaging studies report activation of the same regions, with some recent work suggesting that different components of the frontostriatal-thalamic circuit mediate different symptom clusters (Mataix-Cols et al., 2004). Lesions studies of the effects of focal damage to the ventromedial prefrontal cortex and the basal ganglia have reported the onset of OCD as a sequela of acquired damage (Berthier, Kulisevsky, Gironell, & Heras, 1996; Giedd, Rapoport, Leonard, Richter, & Swedo, 1996; Grados, 2003; Irle, Exner, Thielen, Weniger, & Ruther, 1998; Peterson, Bronen, & Duncan, 1996; Swoboda & Jenike, 1995).

Structural Neuroimaging of OCD. The models described earlier predict trophic changes in key regions of the dysfunctional circuitry. Hyperactivity of the frontal components might lead to expansion of the anterior cingulate gyrus and orbitofrontal gyrus, particularly when subjects are symptomatic. The failure of the basal ganglia to gate sensory inputs might suggest that this structure has sustained subtle damage and may thus be smaller than in healthy populations. Finally, the loss of inhibitory input to the thalamus disinhibits this structure, and a resulting hyperactivity could potentially have trophic effects.

There have indeed been reports of expansion of gray matter in the left anterior cingulate cortex in an unmedicated pediatric population (see Table 3.6; Szeszko et al., 2004). The cortical expansion was specific to the anterior cingulate and not found in other frontal regions such as the superior frontal gyrus, in keeping with the earlier theories of the pathogenesis of OCD. Rosenberg and Keshavan (1998) report a similar increase in the volume of the anterior cingulate cortex in a different population of unmedicated children and adolescents with OCD. In adult populations, there are reports of larger operculum volumes in women with OCD in a region of interest study (Jenike et al., 1996). However, this finding was not replicated by the same group using a semiautomated parcellation technique that measures 10 regions of the frontal; instead, there was reduction in the right inferior frontal and medial frontal cortex (Grachev et al., 1998). Increased cortical density specific to the orbitofrontal cortex has also been implicated in a study of adults with OCD using voxel-based morphometry (Kim et al., 2001). Again, a region of interest

TABLE 3.6 Structural Neuroimaging Studies of Obsessive-Compulsive Disorder

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Luxenberg et al. (1988)	10 Males (child- hood onset OCD) (20.7 \pm 2.1)	10 Males (23.7 \pm 2.6)	CT scans, manual trace of ROI.	Decreased volume of caudate bilaterally.	Patients were heavily comorbid with tic disorder, which may have contributed independently to the volume reduction.
Rosenberg et al. (1997)	13 Males 6 Females (12 \pm 3)	13 Males 6 Females (12 \pm 3)	Manual tracing of region of interest (including entire frontal lobes).	Decreased volume of caudate and putamen.	No volume difference in pre- frontal lobe.
MacMaster, Rosenberg, Keshav- an, & Dick (1999); Rosenberg & Keshavan (1998); Rosenberg et al. (1997)	13 Males 8 Females (7.2–17.7)	13 Males 8 Females (7.2–17.7)	Manual tracing of regions of interest, sig- nal intensity used as measure of myelination.	Increased volume ante- rior cingulate and increased surface area of corpus callosum in OCD, increased signal intensity in anterior genu in OCD.	Abnormalities correlated with symptom severity.
Giedd, Rapoport, Garvey, Perlmut- ter, & Swedo (2000)	24 Males 10 Females (PANDAS assoc OCD and/or tics)	82 Healthy con- trols matched for age and gender	Semiautomated total brain volume, manual tracing of basal ganglia structures.	Enlarged caudate, puta- men, globus pallidus; no diff in thalamus or TBV.	Thalamus as area from single slice.
Gilbert et al. (2000)	7 Males 14 Females (12.35 \pm 2.93)	7 Males 14 Females (12.47 \pm 2.64)	Manual tracing of region of interest.	Increased volume of thal- amus in OCD.	Successful treatment with paroxetine in 10 of the subjects associated with partial normal- ization of the volume of the thalamus.
Szeszko et al. (2004)	7 Males 16 Females (12.3 \pm 2.9)	12 Male 15 Female (13.6 \pm 3.2)	Manual tracing of regions of interest from contiguous 1.5-mm MR images.	Decreased volume of L globus pallidus, no diff in putamen, dec. gm volume in L anterior cingulate.	Conflicts with earlier reports from this center of decreased volume in putamen (Rosenberg et al., 1997). Attributed to sam- ple differences.

approach on the same subjects yielded discrepant results, with a finding of reduced volume of the left orbitofrontal cortex (Kang et al., 2004). Thus, the results of a region of interest approach using operator-defined regions can conflict with the results of automated measures of the same regions on the same subjects, illustrating the complexity of comparing the results of different methodologies.

The finding of enlargement or increased cortical density in the anterior cingulate and orbitofrontal cortex has not always been replicated. One of the largest studies in OCD, on 72 adults with OCD using automated voxel-based methods of determining the volume, demonstrated decrease in the gray matter of the medial orbitofrontal and anterior paracingulate gyrus (Pujol et al., 2004). Several groups, studying both children and adults, have found either a decreased or no difference in the volume of the orbitofrontal cortex (Choi et al., 2004; Szeszko et al., 1999).

The structural picture is also inconsistent in the basal ganglia, with reports in pediatric populations of an increase, decrease, or no change in the volume of the caudate,

putamen, and globus pallidus (Giedd, Rapoport, Garvey, Perlmutter, & Swedo, 2000; A. R. Gilbert et al., 2000; Rosenberg, Keshavan, Dick, et al., 1997; Szeszko et al., 2004). A similar picture emerges in adult studies, with the largest single study reporting an increase in the volume of the basal ganglia, which correlated with the reduction in the orbital and paracingulate cortices (Pujol et al., 2004), but other studies reported either no significant overall change in the basal ganglia of adults with OCD (Aylward, Harris, et al., 1996; Jenike et al., 1996) or even an increase in volume (Scarone et al., 1992).

A developmental perspective may help unravel the factors contributing to this heterogeneity. Findings of an increase in basal ganglia volume have been reported mainly in pediatric populations, in whom many of the subjects had OCD arising in association with streptococcal infection. It is possible that an inflammatory process in these pediatric subjects could account for the findings of increased volume. Differences in the protocols used to define the various components of the basal ganglia are also likely to

account for some of the variance, along with measurement error inherent in manual tracings of the basal ganglia. In this regard, the findings of fully automated methods are of particular interest as they do not rely on arbitrary definitions of regions of interest. Finally, subjects with OCD in each study varied considerably in their comorbidity and history of medication. For example, in the studies of children with OCD that report smaller caudate nuclei, there are high rates of comorbid tic disorders, which may contribute independently to the volume loss (Aylward, Harris, et al., 1996; Luxenberg et al., 1988).

The thalamus serves as the final component of the circuitry held to be dysfunctional in OCD. The cessation of tonic inhibitory input from a dysfunctional striatum in OCD is thought to lead to thalamic hyperactivation, which is then fed forward to the frontal cortex. In children, a marked increase in thalamic volume has been found (A. R. Gilbert et al., 2000). An increase in the density of gray matter of the thalamus has been reported in adults (Kim et al., 2001), although a voxel-based volumetric study did not report increased thalamic volumes (Pujol et al., 2004). Volume change in the thalamus appears to reflect active symptoms as partial normalization of thalamic volume has been reported following successful treatment. One study reported a 25% reduction of the volume of the thalamus in a group of 10 children treated with paroxetine, which correlated significantly with reduction in symptoms (A. R. Gilbert et al., 2000).

White matter changes in OCD are relatively unexplored. There have been several studies examining the corpus callosum, with reports of an overall increase in the surface area of the corpus callosum in children, which correlated with symptom severity (Rosenberg, Keshavan, Dick, et al., 1997). This study used its cross-sectional data on children of different ages to delineate the possible trajectory of corpus callosum development. They reported that healthy children appeared to lag behind children with OCD in corpus callosum size, attaining equivalent posterior body and anterior and middle splenii sizes 7 to 9 years later than OCD patients. The same group further characterized the changes in the corpus callosum by studying changes in signal intensity, an index thought to reflect the degree of myelination (MacMaster, Keshavan, Dick, & Rosenberg, 1999). They found that there was a difference in children with OCD in the signal intensity in the portion of the corpus callosum that connects the ventral prefrontal cortex with the striatum. This finding is in keeping with pathophysiological models and may account for the anomalous interactions between these regions in OCD. The authors hypothesized that

the structural changes in the corpus callosum may reflect either earlier myelination of callosal fibers in children with OCD or a failure of programmed elimination of excessive callosal fibers. By adulthood, myelination is largely complete, and thus size difference in the corpus callosum between adults with OCD and healthy adults would not be predicted. In line with this prediction, Jenike et al. (1996) reported a very slight reduction in the retrocallosal region in 10 adults with OCD.

Turning to other white matter regions, Szesko and colleagues (2004) found no increase in the white matter of the anterior cingulate gyrus despite an increase in the gray matter in a pediatric population. In a large group of adults using automated voxel-based volumetric measures, Pujol and colleagues (2004) found no significant difference in white matter volumes in any brain region. Future work using DTI techniques might allow a more detailed characterization of more subtle changes in white matter in OCD.

Automated techniques such as voxel-based morphometry allow an examination of structural changes throughout the brain without any a priori region of interest. Using these techniques, several unexpected regions of the brain have been demonstrated as structurally anomalous in OCD. In adults, there has been a demonstration of volume loss in the anterior cerebellum (Pujol et al., 2004) and of increased gray matter density in similar regions (Kim et al., 2001). Although the two findings are at odds, they highlight the importance of considering the cerebellum in the pathogenesis of the disorder.

Conclusions. There are several convincing demonstrations of structural alterations in the volumes of the anterior cingulate cortex and orbitofrontal cortex, and, to a lesser extent, components of the basal ganglia and thalamus. Differences in the direction of the change—with some studies reporting increases, other decreases in these regions—are hard to reconcile. Several usual suspects are likely to be at play, including differences in comorbidity in patients with OCD, medication effects, and varying definitions of regions of interest. Developmental factors may also be important as there may be differences in the etiologies of childhood- and adult-onset cases. Many of the structural changes found in OCD may reflect symptom activity only and thus do not give an insight into the underlying structural changes that render individuals susceptible to developing the disorder. Clarifying the nature of structural changes in individuals with OCD changes is important for genetic studies, which increasingly use structural brain changes as an endophenotype.

Although the concept of parallel frontostriatal-thalamic circuits has been extremely fruitful, primate and rat studies suggest that the basic neuroanatomy of the interactions among the cortex, striatum, and thalamus is more complicated than simple parallel loops (Haber & McFarland, 2001; Mailly, Charpier, Menetrey, & Deniau, 2003). Future studies will need to address the additional complexity created by spiraling interactions within the basal ganglia. However, despite these theoretical and practical limitations, the structural findings in OCD impress by virtue of the consistency of the regions that are identified as structurally anomalous.

Disorders with Increased Onset at Adolescence

The final section considers disorders whose incidence rises during puberty and adolescence. This time can be a period of increased stress, as individuals strive to cope with physical and psychological changes amidst the new societal demands of adulthood, and the amount of difficulty with which this transition is navigated can vary widely. In addition, as described in the earlier section on normal neurodevelopment, it is now recognized that these years represent a second critical period of brain development. While the psychological and behavioral difficulties experienced by many adolescents are transitory, in some they are beginnings of what may become chronic psychiatric disorders. The relationship of the brain remodeling such as cortical synaptic pruning occurring during this time with the increasing prevalence of specific psychiatric syndromes such as Schizophrenia and mood disorders is not yet understood but is the subject of increasingly intense inquiry, as recently reviewed by Spear (2000) and Walker, Sabuwalla, & Huot (2004). The extent and complexity of the influence of hormones such as estrogen and testosterone on brain structure and function is just beginning to be appreciated. In addition, there is increasing evidence that the hypothalamic-pituitary-adrenal axis undergoes changes during puberty that may make the adolescent brain more vulnerable to long term effects of stressful experiences than either children or adults (Walker et al., 2004).

One of the challenging aspects to understanding the etiologies of these disorders is determining how genetic factors interact with maturation and with environmental influences to result in the manifestation of the clinical syndrome many years after birth. The most common conceptualization is that of a stress-diathesis model, in which genetically mediated vulnerabilities interact with environmental stresses to trigger the onset of symptoms. Maturation may affect the types of stresses that can be en-

countered, for example, typical trials of adolescence such as leaving home or increasing access to potentially neurotoxic types of substance abuse. The interaction will be different depending on the state of brain maturity. In addition, as previously described in the example of Rett syndrome, the stage of maturation can have a major effect on the expression of particular genes. It is thought that the triggering of new gene expression by changing hormone levels during puberty may be one of the factors increasing the incidence of disorders such as mood disorders and Schizophrenia.

Studying individuals as early as possible in the course of the disorder provides an approach to disentangling these factors and identifying genetic components informative regarding the pathophysiology of the syndrome. If expression of symptoms occurs in response to a combination of biologic vulnerabilities and environmental stressors, then those who become ill earlier in life may have had a more severe biological “loading” to begin with, and this may thus be easier to describe than in individuals who become ill later. In addition, attempts of an individual and/or his or her family to compensate for the presence of a disorder may introduce further relatively nonspecific alterations in the developmental trajectory that can obscure attempts to isolate contributions of the genetic component. The use of brain structural features from imaging studies as endophenotypes may help to clarify this, but interpretation of imaging studies is also challenged by difficulty of determining what findings are related to vulnerability, are evidence of disease progression, or represent compensatory reactions to a damaged system elsewhere in the brain.

In this section we review structural imaging findings in Schizophrenia, depression, and bipolar disorder, continuing to emphasize studies performed in children and adolescents with discussion of relationship of childhood and adolescent forms of the illnesses to findings in adults.

Childhood-Onset Schizophrenia

Schizophrenia is a disorder characterized by onset of psychotic symptoms and loss of function, most typically during late adolescence and young adulthood. It affects approximately 1% of individuals worldwide. Function usually begins to deteriorate during a period called the *prodrome*, a period of increasingly severe symptoms that can last weeks to years. At some point symptoms become overwhelming, often in the form of a “first break.” Although most individuals recover from their first episode the risk of relapse is high, and after a period of years impairment tends to become chronic. Although Schizophrenia’s frequent occurrence and high morbidity have made it

one of the most thoroughly studied of the psychiatric disorders, its etiology and pathophysiology remain obscure.

It is now widely accepted that Schizophrenia is a neurodevelopmental disorder, supported by a significant genetic component, higher incidence of neurodevelopmental anomalies, and presence of nonspecific premorbid cognitive and neurologic abnormalities. It is not known what triggers the onset of psychotic symptoms in the 2nd or 3rd decade of life. Understanding the biological substrate of Schizophrenia is further complicated by factors related to having a chronic psychotic disorder such as exposure to medication or socioeconomic hardship.

COS is defined as onset of psychotic symptoms before the 13th birthday. It has been recognized since the early twentieth century (Kraepelin, Barclay, & Robertson, 1919) as a rare and severe form of the illness, which occurs one-fiftieth as frequently as adult-onset type (Beitchman, 1985; W. H. Green, Padron-Gayol, Hardesty, & Bassiri, 1992; Karno, Golding, Sorenson, & Burnam, 1988; Kramer, 1978; Volkmar, Cohen, Hoshino, Rende, & Paul, 1988). COS appears to be clinically continuous with adult-onset schizophrenia (AOS; Gordon, 1992; W. H. Green et al., 1992; Russell, Bott, & Sammons, 1989; Spencer & Campbell, 1994), and children can be diagnosed with the unmodified *DSM* criteria for Schizophrenia. COS subjects resemble poor outcome adult cases with respect to the insidious onset of symptoms and poor premorbid functioning (Alaghband-Rad et al., 1995; W. H. Green et al., 1992; Hollis, 1995). However, early developmental abnormalities in social, motor, and language domains are more striking in COS than in AOS. Some of the interest in studying this rare population arises from the hypothesis that Schizophrenia in its early-onset form may have unique or more salient pathophysiology and genetic risk factors, as demonstrated in other disorders such as diabetes (Childs & Scriver, 1986). The incidence of Schizophrenia steadily increases with age. Early-onset schizophrenia (EOS) is a term generally considered to include individuals with onset prior to adulthood.

Imaging Studies. Schizophrenia was the first psychiatric disorder to be studied using structural neuroimaging techniques (Johnstone, Crow, Frith, Husband, & Kreel, 1976), and has been the subject of an enormous and growing number of structural neuroimaging studies since (see Table 3.7). Although findings have varied between studies, likely related to some of the confounding issues stated above, some findings have been relatively consistent. Most studies have found decreased total cerebral volume and enlarged ventricles. Smaller mesial temporal lobe structures

have been the most consistently reported regional abnormality (Andreasen et al., 1986, 1990; Bilder et al., 1994; Breier et al., 1992; DeLisi et al., 1991; Jernigan, Zisook, et al., 1991; Marsh, Suddath, Higgins, & Weinberger, 1994; Shenton et al., 1992; Swayze, Andreasen, Alliger, Yuh, & Ehrhardt, 1992). Caudate volumes have been reported as enlarged in individuals who had been exposed to "typical" antipsychotics for prolonged periods, an effect which diminished when individuals were placed on the atypical antipsychotic clozaril (Chakos et al., 1994; Elkashef, Buchanan, Gellad, Munson, & Breier, 1994). Decreased thalamic volume has also been described (Andreasen et al., 1994; Flaum et al., 1995).

With the exception of the NIMH COS study described below there have been few neuroimaging studies of COS, due to the rarity of individuals with very early onset. An MRI case study of a 10-year-old boy with COS reported ventriculomegaly and a small left cerebellum (Woody, Bolyard, Eisenhauer, & Altschuler, 1987). A study of 6 children with Schizophrenia, schizophreniform disorder, or other psychosis found larger ventricular volume in three of the subjects (Hendren, Hodde-Vargas, Vargas, Orrison, & Dell, 1991). A third study likewise found enlarged ventricles in a group of 15 schizophrenic or schizophreniform disorder adolescents (mean age 16.5 years; S. C. Schultz et al., 1983).

In the largest study to date, the Child Psychiatry Branch of the NIMH has been enrolling patients in a longitudinal neuroimaging study for over a decade. Over 75 patients have participated to date, with an average age of psychosis onset of approximately 10 years and average age at study entry of approximately 14 years. Subjects undergo extensive screening and diagnostic testing to verify diagnosis. Those who participate undergo structural brain MRI scans at 2-year intervals in conjunction with clinical and neuropsychological follow-up measures and also contribute DNA for genetic analyses. The structural neuroimaging data is analyzed using a variety of automated, semi-automated and manual techniques, providing cross-sectional and longitudinal measures of total brain volume, gray and white matter, regional volumes, and cortical thickness measures (Collins, Zijdenbos, Baaré, & Evans, 1999; Thompson, Vidal, et al., 2001).

Currently available studies indicate that children with Schizophrenia show increased lateral ventricular volume, decreased total brain volume, decreased gray matter volume, and increased basal ganglia volume (probably secondary to medication effect; Frazier, Giedd, Hamburger, et al., 1996; Kumra et al., 2000; Rapoport et al., 1997, 1999; Sowell et al., 2000). There is less agreement with respect to reduced

TABLE 3.7 Structural Neuroimaging Studies of Childhood Onset Schizophrenia

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Schulz et al. (1983)	15 patients with Schizophrenia or schizophreniform disorder (16.5)	18 age matched healthy controls 8 borderline patients	CAT study of ventricle volumes.	Ventricles enlarged in Schizophrenia and schiz- ophreniform compared to other two groups.	Increased ventricular brain ratio related to poorer treatment response.
Woody, Bolyard, Eisenhauer, & Altschuler (1987)	10 year-old boy		CAT and MRI.	Enlarged ventricles and dec. left cerebellum.	Case study.
Hendren et al. (1995)	6 Males 6 Females (8–12) with early psychotic symptoms	12 subjects matched on age, gender, SES	1.5 coronal images, manual ROI.	Dec. amygdala and mesial temporal cortex volumes, decreased area of corpus callosum; decreased asymmetry measures.	MRS data obtained on subset of patients, trend to decreased NAA:Cre ratio.
Frazier et al. (1996)	COS: 13 Male 8 Females (14.6 \pm 2.1)	33 controls matched for age, sex, height, weight	1.5T, 1.5 mm axial con- tiguous slices, semi- automated segmentation and manual tracing of ROIs.	COS smaller total cere- bral volume and midsagitt- al thalamic area, larger ventricular volume in the COS group; COS larger basal ganglia volumes.	NIMH study. Enlarged basal ganglia possibly related to medication.
Jacobsen et al. (1997)	12 Males 12 Females with COS (14.1 \pm 2.1)	28 Males 24 Females (14.3 \pm 2.0)	1.5T, 1.5 mm axial con- tiguous slices, semi- automated segmentation and manual tracing of cerebellar ROIs.	COS had smaller vol- umes of vermis and vol- ume and midsagittal areas of posterior infe- rior cerebellar lobe.	NIMH study. Findings present after correction for total cere- bral volume.
Friedman et al. (1999)	15 Male 5 Female (14.7 \pm 2.2)	Healthy controls: 9 Male 7 Female (15.6 \pm 1.8) Bipolar Disorder: 8 Male 7 Female (15.3 \pm 2.4)	T2/Spin density weighted axial images, 5 mm slice, 2 mm gap; manual ROIs.	Patient groups did not differ from each other. Combined patients groups show larger ven- tricles and smaller cere- bral volume.	
Kumra et al. (2000)	COS: 25 Male 19 Female (14.4 \pm 2.3) PDNOS: 22 Male 5 Female (12.3 \pm 2.9)	73 Male 33 Female, age matched sepa- rately to COS and PDNOS groups	1.5T, 1.5 mm axial con- tiguous slices, semi- automated segmentation and manual tracing of ROIs.	COS: smaller cerebral volume, smaller mid- sagittal thalamic area, COS and PDNOS larger ventricles than controls.	NIMH study: Psychotic Disor- der Not Otherwise Specified (PDNOS).
Sowell et al. (2000)	COS: 3 Males 6 Females (14.41.5T, 1.5 mm axial contiguous slices, semiauto- mated segmenta- tion and manual tracing of ROIs)	2 Males 8 Females (12.1 \pm 2.9)	1.5T T1 coronal 1.4 mm contiguous slices, semi- automated segmenta- tion, voxel based morphometric analysis.	Larger ventricles, pre- dominantly in the poste- rior horns of the lateral ventricles, and midcal- losal, posterior cingu- late, caudate, and thalamic abnormalities.	Average age of diagnosis 11.0 \pm 2.9.

TABLE 3.7 Continued

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Badura et al. (2001)	19 children with onset schizophrenia prior to age 14	Age and gender matched controls from children scanned for non-neurologic reasons	CAT study of ventricle volumes.	Increased ventricle size at onset seen only in those with onset prior to age 12, ventricle size also correlate with length of illness.	11 scans made within first year after onset of illness, rest between 2–9 years later.
Thompson, Vidal, et al. (2001)	12 COS (13.9 \pm 0.8)	12 Healthy con- trols (13.5 \pm 0.7) 10 Age-matched MDI	Longitudinal study with MRI at 3 time points, approx 2 years between scan; 1.5T, 1.5 mm axial contiguous slices, semiautomated cortical thickness measures using sulcal landmarks.	Dynamic pattern of marked gray matter loss in COS group, begin in parietal region, healthy controls show dynamic but much smaller decrease in cortical thickness; MDI group intermediate.	NIMH study: MDI = Multidi- imensionally impaired. MDI group provide comparison group matched for medication expo- sure. Decreases in cortical thickness correlate with clinical status.
James, Javaloyes, James, & Smith (2002); James, James, Smith, & Javaloyes (2004)	Early-onset schizophrenia: 9 Males 7 Females 16.6 (\pm 1.6)	Controls: 9 Males 7 Females	Longitudinal study with avg. 2.5 years between scans, 1.5 T1 coronal 3 mm contiguous slices, manual ROI.	Baseline smaller pre- frontal cortex and thala- mus, borderline larger ventricles in EOS, no evidence of progression over time during late adolescence.	Limited by small sample size.
Gogtay, Giedd, et al. (2004)	COS: 19 Males 4 Females (13.9 \pm 2.5) MDI: 16 Males 3 Females (13.3 \pm 3.1)	Controls: 32 Male 6 Females (13.3 \pm 3.1)	Longitudinal study with average of 3 years between scans; 1.5T, 1.5 mm axial contigu- ous slices, automated measurement of lobar gray matter volumes.	COS group had signifi- cantly greater loss of GM than MDI or normal controls, which did not differ from each other.	NIMH study: MDI = Multidi- imensionally Impaired. See also Rapoport (1997, 1999), Jacob- sen (1998), Giedd (1999), Keller (2003), and Sporn (2003) for other reports from this lon- gitudinal study.

volume of medial temporal lobe structures (Jacobsen et al., 1996; Matsumoto, Simmons, Williams, Hadjulis, et al., 2001; Matsumoto, Simmons, Williams, Pipe, et al., 2001).

An updated comparison of 60 COS (mean age 14.27 + 2.41) with 110 (mean age 14.18 + 2.44) age- and sex-matched healthy volunteers extended the previous studies (Gogtay, Giedd, et al., 2004), finding that the smaller cerebral volume in COS was largely due to a robust (10%) decrease in cortical gray matter, whereas the adjusted white matter volume did not differ significantly between the COS and healthy groups. Of note is the striking reduction in parietal gray matter volume, which may be characteristic of EOS. Frontal and occipital gray matter were also reduced, albeit less extremely, only the volume of the temporal gray matter was not different between COS patients and healthy controls.

The longitudinal study design of the NIMH study has allowed the description of progressive brain volume loss in COS. It appears to be more severe than what is seen in most studies of adults. Increasing ventricular volume and

decreasing total cortical, frontal, temporal, and parietal gray matter volumes were seen across 2, 4, and 6 years after their initial scan. Here, too, regional gray/white segmentation showed the progressive loss to be for gray matter only (Giedd, Jeffries, et al., 1999; Jacobsen et al., 1998; Rapoport et al., 1997, 1999).

The rapid changes seen for COS most likely occur only during a circumscribed period, as age of onset does not appear significantly related to decreased cortical gray matter loss in adult patients (Lim et al., 1996; Marsh et al., 1997). Adolescence may provide a time-limited window in which progressive brain changes in Schizophrenia are most easily observed. This is supported by a very recent longitudinal analysis of our quantitative brain imaging data for a larger group of 36 COS patients with one or more scans, suggesting that the rate of gray matter loss slows as these COS patients reach age 20 (see Figure 3.9; Sporn et al., 2004).

This is in accordance with another follow-up study of adolescent-onset schizophrenia that documented substantially smaller prefrontal cortex and thalamus in affected

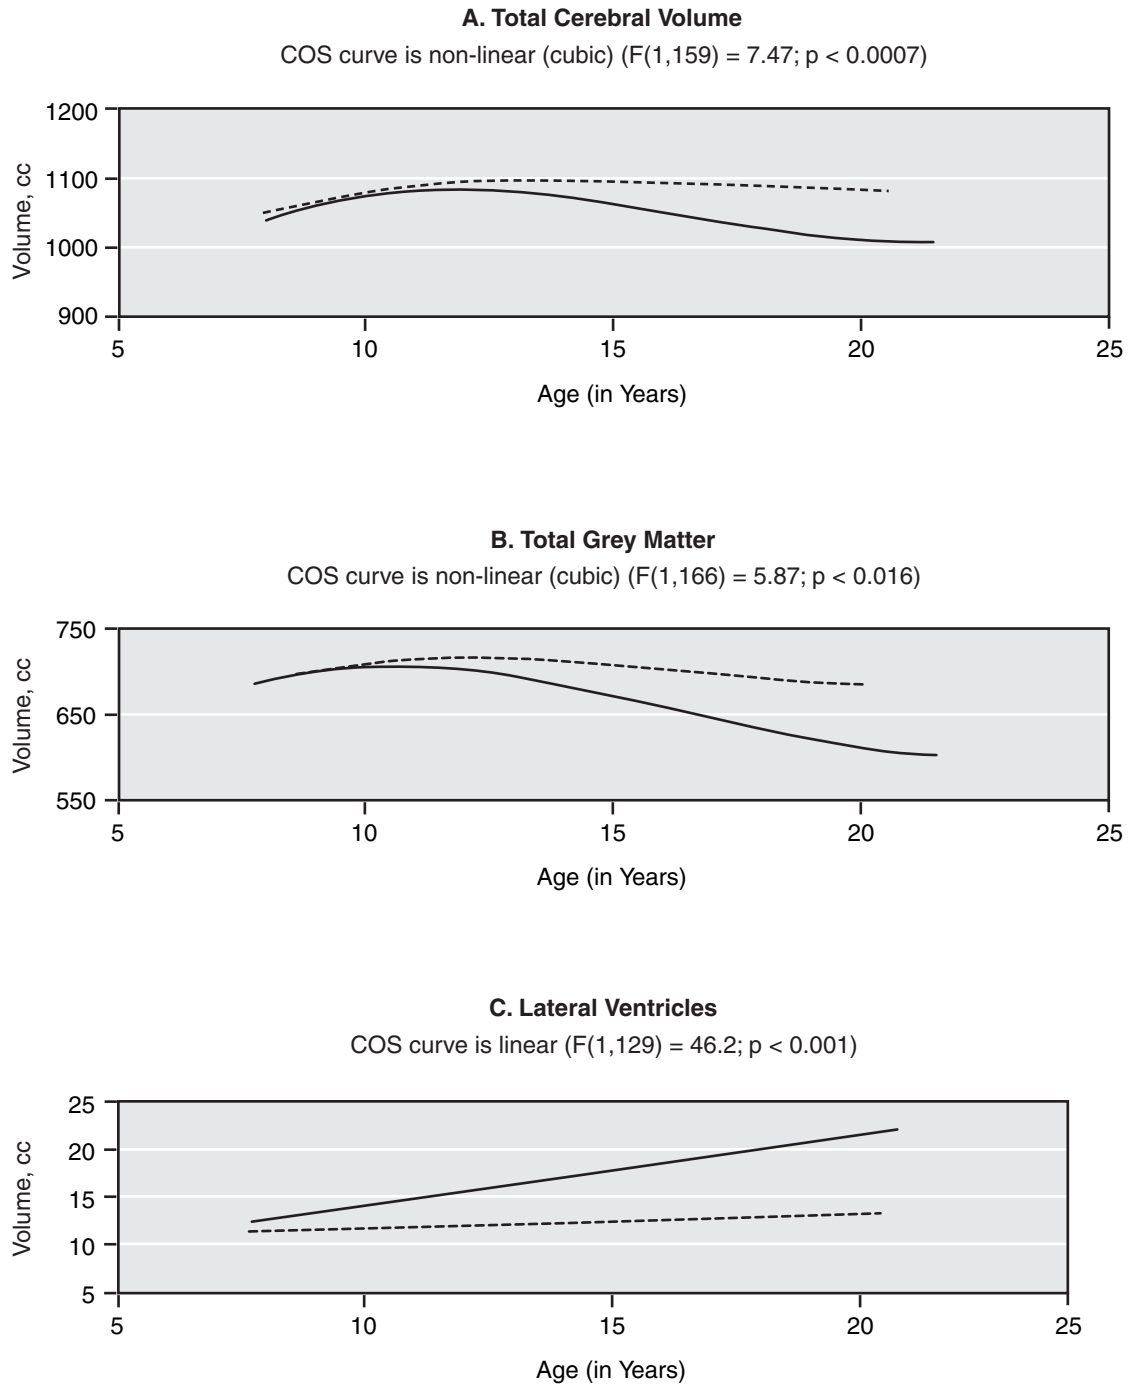

Figure 3.9 Developmental pattern for selected anatomic brain MRI measures for childhood Onset Schizophrenia ($n = 57$, 61% males, 115 scans) and healthy controls ($n = 60$, 63% males, 119 scans). Non-linear curves for total cerebral volume and total gray matter indicate decline in rate of loss that approaches zero at approximately age 21. Lateral ventricular enlargement however remained linear within the studied age period. *Source:* From “Pervasive Developmental Disorder and Childhood-Onset Schizophrenia: Comorbid Disorder or a Phenotypic Variant of a Very Early Onset Illness?” by A. L. Sporn et al., 2004, *Biological Psychiatry*, 55(10), pp. 989–994.

subjects but little evidence for progression over time between ages 18 to 20 (James, James, Smith, & Javaloyes, 2004; James, Javaloyes, James, & Smith, 2002). Recent studies of AOS, using comparable methodology, have found relatively subtle progressive loss of brain matter (DeLisi, 1999a, 1999b; Gur et al., 1998; Lieberman et al., 2001; Mathalon, Sullivan, Lim, & Pfefferbaum, 1997). An effect size comparison documents that the progressive changes are more striking during adolescence, at least for very early onset cases (Gogtay, Giedd, Janson, & Rapoport, 2001). Similarities between the follow-up imaging studies of COS and AOS include progressive ventricular expansion and cortical gray matter loss mostly in the frontal and temporal region. In addition to the frontal and temporal gray matter loss, the COS population also showed significant parietal gray matter loss.

Recently, the NIMH group and collaborators from UCLA used a computational tensor-matching strategy to compare the 3-dimensional distribution of gray matter across time on a voxel-by-voxel basis. Regionally specific cortical development across time and between subject groups was demonstrated. In the COS patients, the parietal gray matter volume loss occurs initially, with frontal and temporal gray matter changes appearing later across the adolescent years (Thompson, Vidal, et al., 2001). This is in support of the findings presented earlier, using the more automated quantitative approach and indicating that the progressive gray matter loss in COS takes place in a regular posterior-anterior wave-like fashion that was seen in all subjects in the COS study. Some support of this back-to-front wave of cortical loss as intrinsic to Schizophrenia is provided by a study of full siblings of COS patients. A recent comparison of 15 healthy siblings of COS and 32 age- and sex-matched community controls showed that the COS siblings have smaller parietal gray matter volume (Gogtay, Sporn, et al., 2004). Although limited by small sample size, these familial findings, if replicated, would suggest that a back-to-front pattern (parieto-frontal) of gray matter loss could be a trait marker in Schizophrenia.

The prospective studies have also enabled researchers to relate brain loss to medication effects. A 2-year follow-up study was done with eight patients taking typical neuroleptics at the time of the first scan and maintained on clozapine for 2 years prior to the second scan (Frazier, Giedd, Kaysen, et al., 1996) because of controversy related to the effect of neuroleptics on reported basal ganglia enlargement in Schizophrenia (Chakos et al., 1994; Elkashef et al., 1994; Keshavan et al., 1994). On follow-up, the clozapine-maintained COS group, but not eight age- and sex-matched controls also receiving a 2-year follow-up scan, demon-

strated decreased caudate and putamen volumes over time. These findings are consistent with the hypothesis that basal ganglia enlargement in COS is secondary to medication effects.

Although the MRI studies of COS have extended our knowledge of abnormal neurodevelopment, the studies discussed do not yet allow differentiation between several current alternative explanations for the precise nature of the abnormal process occurring. One version of the neurodevelopmental hypothesis of Schizophrenia proposes an early (and fixed) lesion in the prenatal or perinatal period, resulting in a disturbed late maturational response (Weinberger, 1987). This implies that specific early lesions can disrupt the later maturing regions such as the frontal-limbic circuitry and that such effects could be interaction of genetic variability (and vulnerability) and environmental factors (Lipska et al., 1995; Lipska & Weinberger, 2002). A second formulation of the neurodevelopmental hypothesis was made by Woods (1998). Based in part on the normal skull size but increased intracranial CSF space in Schizophrenia, Wood proposed that the illness be considered a progressive neurodevelopmental disorder. Neurodevelopmental genes may have multiple roles across different time periods, and etiological agents causing abnormalities in early development may have related but different effects at later stages depending on gene-environment interactions. Finally, it is possible that the progressive brain changes represent a plastic response of the brain to the illness. However, a plastic brain response to illness cannot represent the only basis for these changes, as healthy siblings of COS patients have also shown relative cortical gray matter decrease on initial scans.

Affective Disorders

Affective disorders are the most common psychiatric syndromes and among the highest causes of global burden due to disability worldwide (Costello et al., 2002). Their key features are abnormally elevated or depressed mood (or both), in conjunction with neurovegetative symptoms. Disordered thought, abnormal reality testing, and cognitive deficits may also be present during severe affective episodes (American Psychiatric Association, Task Force on *DSM-IV*, 2000). Differentiating pathological affective episodes from normal responses to life events, such as grief in response to a loss, can be quite difficult, and often represents making a division within a continuum of severity of intensity or duration.

The study of brain structural changes associated with affective disorders is much less developed than in Schizophrenia. To some extent, this may relate to the more common view that affective disorders fall more on the "functional" than

“organic” end of the psychiatric spectrum (Harrison, 2002). However, it is becoming clearer that the course of illness in many individuals with bipolar or unipolar mood disorders is chronic, and at least in the case of bipolar disorder (BD), may also be associated with gradual deterioration in function. The presence of clear genetic predispositions to both depression and bipolar disorders also motivates the use of structural imaging techniques to search for brain changes that could serve as the source of vulnerability to mood symptoms.

Many of the same considerations apply to neuroimaging studies in affective disorders as already discussed in Schizophrenia. Studies in affective disorders have tended to frequently report conflicting results, possibly related to the small sample sizes of the studies, uncontrolled or unknown medication status, and heterogeneous clinical presentation (Beyer & Krishnan, 2002; Brambilla, Barale, Caverzasi, & Soares, 2002; Strakowski, Adler, & DelBello, 2002; Videbech & Ravnkilde, 2004).

A further confounding factor that has not yet received very much attention is how symptoms and physical findings in chronic affective disorders may change over the lifetime, similarly if to a less severe extent than what is seen in Schizophrenia (Kaufman, Martin, King, & Charney, 2001; Kessler, Avenevoli, & Ries Merikangas, 2001). Affective disorders, like Schizophrenia, most frequently appear during adolescence. There is evidence to suggest that there may be some differences between depression and BD in children compared with adults. For example, depression in childhood is often associated with irritability in addition to or instead of a sad mood, and tricyclic antidepressants, which are effective in adults, do not appear to show a similar benefit in children (Kaufman et al., 2001). Juvenile BD has been the object of considerable controversy, as it has been proposed that children may have BD at a rate much higher than once thought, but with a phenotype differentiated from that in adults by a high prevalence of rapid or continuous mood cycling, mixed states, and presence of ADHD symptoms (“National Institute of Mental Health Research Roundtable on Prepubertal Bipolar Disorder,” 2001; Geller & Luby, 1997). There is ongoing debate in both Major Depressive Disorder and BP about whether duration criteria for episodes should be altered for younger populations (Pruett & Luby, 2004). Longitudinal studies to track how and whether a childhood affective disorder phenotype changes with maturity are currently in process. The first reports from a study in children meeting conservative criteria for BP have shown stability of symptoms during early adolescence (Geller, Tillman, Craney, & Bolhofner, 2004). More of such studies will be necessary to resolve questions about the relation-

ship of the forms that appear during different stages of development (Pruett & Luby, 2004).

Bipolar Disorder

Bipolar Affective Disorder is characterized by the presence of manic or hypomanic episodes interspersed with periods of depression or euthymia. It was first described by Kraepelin, Barclay, and Robertson (1919) in his fundamental division of psychotic disorders as having an intermittent course as opposed to the ongoing deterioration characteristic of dementia praecox, which came to be called Schizophrenia. The current *DSM* describes two variations of the disorder: BP I, which has manic or mixed episodes with or without depressed episodes, and BP II, which requires a combination of hypomanic and major depressive episodes (American Psychiatric Association, Task Force on *DSM-IV*, 2000).

Like many other psychiatric syndromes, BP appears to be a complex genetic disorder arising in response to a combination of environmental, genetic, and epigenetic influences (Craddock & Jones, 2001; Petronis, 2003). The prevalence in adolescents and adults is approximately 1% to 3% (Kashani et al., 1987; Lewinsohn, Klein, & Seeley, 1995); in first-degree family members it increases to approximately 7%, and in monozygotic twins to 60% (T. D. Gould, Quiroz, Singh, Zarate, & Manji, 2004). Unlike unipolar Major Depressive Disorder, there does not appear to be a sex differential in BP (Biederman et al., 2004). Current controversies about the proper diagnostic criteria for BP in children make prevalence difficult to estimate, but it has been traditionally accepted that onset is less frequent in children (Akiskal et al., 1985). There is some evidence from previous cross-sectional studies and current longitudinal studies that earlier-onset cases show a more severe phenotype and higher rate of affected family members, similar to what is seen in Schizophrenia and many nonpsychiatric medical disorders (Geller et al., 2004; McGlashan, 1988).

BP appears to be associated with abnormalities in the corticolimbic and corticostriatal brain circuits responsible for the regulation of emotion. Although the source of this abnormality is not known, there has been some intriguing evidence of potential abnormalities of signaling pathways active in cellular neurogenesis and resilience (T. D. Gould et al., 2004; Manji & Lenox, 2000). Structural imaging studies in adults with BP have not generally shown global differences in brain volume, supporting more regional effects than seen in an illness such as Schizophrenia (Soares, 2003). Although the literature has a relative preponderance of small studies with conflicting results, more commonly reported findings include decreased volume of the subgen-

ual prefrontal cortex (SGPFC; a portion of the anterior cingulate) and increased volumes of subcortical structures including the amygdala, basal ganglia, and thalamus (Blumberg, Charney, & Krystal, 2002; Brambilla, Haren-ski, et al., 2003; Sheline, 2003). Potential abnormalities in white matter have received relatively little attention until recently, despite increased white matter hyperintensities (WMH) being the single most commonly found feature in BP (Altshuler et al., 1995). The first DTI study in BP in adults was recently published and reported significantly decreased fractional anisotropy in prefrontal white matter (Adler et al., 2004).

Imaging Studies. There have been few structural imaging studies in children and adolescents with BP (see Table 3.8). Studies of temporal lobe structures have had inconsistent findings. Blumberg et al. (2003) scanned 36 individuals with BP I and 56 matched controls. She was able to compare separate groups of adolescents and adults. Similar results were found in both groups: The amygdala was significantly smaller, unlike findings in previous studies of adults, and the hippocampus was slightly smaller but did not reach significance. DelBello (DelBello, Zimmerman, Mills, Getz, & Strakowski, 2004) also found smaller amygdala volumes in her adolescent sample. B. K. Chen et al. (2004) and H. H. Chen et al. (2004) reported on a sample of adolescents with BP I, BP II, and BP-NOS and also found decreased volume of the left superior temporal gyrus (STG) and a trend toward a smaller left amygdala, STG white matter volume was smaller bilaterally. No differences were found in the hippocampus or total temporal lobe volume. Wilke and colleagues (Wilke, Kowatch, DelBello, Mills, & Holland, 2004) compared a group of 10 adolescents with BP against 26 matched archived control scans using both region of interest and voxel based methods. They found larger basal ganglia using both methods. Decreased gray matter volume in the left SGPFC and regions of the medial, temporal, and orbitofrontal lobes was seen using the voxel based method alone.

A group at the University of Cleveland compared adolescents with BP I, Schizophrenia, and controls (Dasari et al., 1999; Friedman et al., 1999). They did not find differences between the BP and schizophrenic groups in measures of total brain volume and sulcal CSF, but the two groups together had a smaller total brain volume, increased sulcal prominence, and decreased thalamic volumes compared with controls. The BP subjects had increased numbers of white matter hyperintensities (WMH) compared with the schizophrenic and control groups (Pillai et al., 2002). Two other separate research groups also identified increased

WMH in children and adolescents with BP I (Botteron, Vannier, Geller, Todd, & Lee, 1995; Lyoo, Lee, Jung, Noam, & Renshaw, 2002). Although the pathogenic significance of WMH is not clear, they have been found to be associated with increased water density in the affected area, potentially due to vascular abnormalities (Lyoo et al., 2002).

Depression

Depression is much more common and disabling in children and adolescents than once believed (Kaufman et al., 2001). The prevalence has been estimated at 2% in children (Kashani et al., 1983; Kashani & Ray, 1983) and 5% and 8% in adolescents (Lewinsohn, Clarke, Seeley, & Rohde, 1994), although the National Comorbidity Survey found a lifetime prevalence of *DSM-III-R* Major Depressive Disorder to be 14% by the end of adolescence (Kessler et al., 2001; Kessler & Walters, 1998). Early-onset depression appears to be associated with a higher risk of recurrence and more long-term morbidity (Kessler et al., 2001). It has become increasingly clear that the neurobiology of depression is different among children, adolescents, and adults on multiple measures, as addressed in a comprehensive review by Kaufman et al. (2001).

Imaging Studies. Studies of brain structure in adults with Major Depression have had highly variable results, but a few findings appear to be relatively consistent (see Table 3.9). Smaller prefrontal volume is more consistently found in adults with unipolar depression than in BD. Reduced volumes of the caudate and putamen have also been reported by several studies, although not all (Beyer & Krishnan, 2002; Lacerda et al., 2003; Pillay et al., 1998). Few studies have examined the cerebellum; two of these reported decreased cerebellar volumes (Escalona et al., 1991; Shah et al., 1992; Yates, Jacoby, & Andreasen, 1987). The relationship of the hippocampus to cognitive functions frequently impaired in depression and the observed sensitivity of the hippocampus to stress in animal models have made it the object of much more scrutiny (Campbell & MacQueen, 2004; Campbell, Marriott, Nhamias, & MacQueen, 2004). Findings have been inconsistent, although a recent meta-analysis by Videbech and Ravnkilde (2004) concluded that the evidence supported a reduction of hippocampal volume of 8% on the left side and 10% on the right side.

Depression, like BD, has been associated with a high rate of WMH, particularly in late-life depression (Coffey, Figiel, Djang, Saunders, & Weiner, 1989; Coffey et al., 1987; Lee et al., 2003; Soares & Mann, 1997; Takahashi et al., 2001; Taylor et al., 2003; Tupler et al., 2002).

TABLE 3.8 Structural Neuroimaging Studies of Bipolar Disorder

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Blumberg et al. (2003)	Adult BP 22 (age 23–54) 12 Female 10 Male Adol. BP 14 (10–22) 8 Female 6 Male	Adult 33 (24–57) 17 Female 16 Male Adol. 23 (10–23) 10 Female 17 Male	1.5T T1 1.2 mm con- tiguous slices, manual parcellation.	Amygdala sig. smaller, hippocampus trend towards smaller size.	Findings not show age inter- action.
DelBello, Zimmerman, Mills, Getz, & Strakowski (2004)	14 Male 9 Females (16.3 \pm 2.4)	11 Male 9 Female (17.2 \pm 1.9)	1.5T T1 1.5 mm con- tiguous axial slices, manual parcellation.	Smaller TCV, amygdala, larger putamen in pts.	
Friedman et al. (1999)	15 Male 5 Female (14.7 \pm 2.2)	Healthy controls: 9 Male 7 Female (15.6 \pm 1.8) Bipolar Disorder: 8 Male 7 Female (15.3 \pm 2.4)	T2/Spin density weighted axial images, 5 mm slice, 2 mm gap; manual ROIs.	Patient groups did not differ from each other. Combined patients groups show larger ven- tricles and smaller cere- bral volume.	
Pillai et al. (2002)	15 Male 5 Female (14.7 \pm 2.2)	Healthy controls: 9 Male 7 Female (15.6 \pm 1.8) Bipolar Disorder: 8 Male 7 Female (15.3 \pm 2.4)	T2/Spin density weighted axial images, 5 mm slice, 2 mm gap; manual ROIs.	BP had increased white matter hyperintensities compared to other two groups.	Same study population as in Friedman (1999).
Lyoo, Lee, Jung, Noam, & Renshaw (2002)	Pt. group includ- ing mix of SCZ (42), BP (56), MDD (94), CD/ADHD (103) 30 other diagnoses as neurotic (12.4 \pm 2.7)	83 control	4-point rating scale of WMH (Coffee 1990 Am J Psych).	WMH sig higher in frontal lobes of BPAD, MDD, and CD/ADHD groups.	WMH = White matter hyperintensities.
Chen et al. (2004)	8 Females 8 Males (16 \pm 3; 12 BPI, 3BPPII, 1 BPNOS)	9 Females 12 Males (17 \pm 4, 9)	1.5 mm contiguous coronal slices; semiau- tomated segmentation; manual trace of hp, amyg, temp lobe, ICV.	Trend to smaller left amygdala in BPAD, in BPADI males L amyg- dala had positive corr with age, controls had inverse corr.	Cross-sectional study.
Chen et al. (2004)	8 Females 8 Males (16 \pm 3; 12 BPI, 3BPPII, 1 BPNOS)	9 Females 12 Males (17 \pm 4, 9)	1.5 mm contiguous coronal slices, semiau- tomated segmentation, ROI tracing of STG.	Smaller STG wm volume bilaterally, smaller total STG vol on left, no other diffs.	Same subjects as above.
Wilke, Kowatch, DelBello, Mills, & Holland (2004)	5 Male 5 Female (14.47 \pm 1.81)	26 Male 26 Female (14.52 \pm 1.29)	3T T1 1.5 mm contigu- ous slices, voxel based morphometry and man- ual ROI.	ROI: larger basal gan- glia, larger L temporal lobe; VBM: Pt larger gm volume in anterior puta- men, head of caudate; decr subgenual of L ant cingulated; medial tem- poral, orbito-frontal.	

TABLE 3.9 Structural Neuroimaging Studies of Major Depressive Disorder

Study	Patients (Mean Age \pm SD, or Range)	Control Subjects	Method	Findings	Comments
Steingard et al. (1996)	30 Males 35 Female (13.42 \pm 2.32)	13 Male 5 Female Nondepressed psychiatric controls (10.78 \pm 2.92)	1.5T T1 axial 5 mm slices with 1.5 mm gap, manual ROI volumes.	Depressed subjects had smaller ratio of frontal lobe volume to total volume, larger ventricular volumes.	Retrospective chart review and reanalysis of clinical MRIs, images redigitized from film.
Botteron, Raichle, Drevets, Heath, & Todd (2002)	30 Early onset females (20.2 \pm 1.6) 18 Later onset 35.8 \pm 8.1	8 Early age matched controls 9 Later onset age matched controls	1.5T 1 mm contiguous slices, manual parcellation.	L subgenual prefrontal cortex smaller in both groups of patients, no correlation with age.	Subjects all female.
Nolan et al. (2002)	10 Male 12 Female (9–17 yrs)	10 Male 12 Female Matched pairwise	1.5T 1.5 mm coronal contiguous slices, manual parcellation.	Larger PFC and PFC wm in non-familial MDD.	Psychotropic-naïve subjects with and without 1st deg relative with MDD.
MacMillan et al. (2003)	10 Male (13.8 \pm 2.7) 13 Female (14.22 \pm 1.81)	10 Male 13 Female Matched pairwise with subjects	1.5T 1.5 mm coronal contiguous slices, manual parcellation of amygdala and hippocampus.	Increased L amygdala:hippo ratio, hippocampal and amygdala volumes not differ when control for ICV and age.	Psychotropic-naïve subjects, some variation in tracing method used.
MacMaster & Kusumakar (2004)	8 Males 9 Females (14.06 \pm 1.98)	8 Males 9 Females Matched pairwise	1.5T 1.5 mm coronal contiguous slices, manual parcellation.	L hippocampus smaller in patients.	9 of patients were psychotropic-naïve.
Rosso et al. (2005)	3 Male 17 Female (15.35 \pm .34)	8 Male 16 Female (14.08 \pm .31)	1.5T 1.5 mm coronal contiguous slices, manual parcellation.	Amygdala smaller bilaterally in subjects.	

One initial study of white matter structure in late-life depression using DTI reported significantly decreased fractional inositivity in the region lateral to the anterior cingulate, which correlated with stronger family history of depressive disorders and poorer outcome (Taylor et al., 2001). Another study focused on the dorsolateral prefrontal cortex, which has been shown to have decreased metabolism associated with active depression in multiple functional studies, and found lower fractional inositivity in the right superior prefrontal cortex, even after controlling for age, sex, hypertension, and cardiovascular status (Taylor, MacFall, et al., 2004).

Structural neuroimaging studies in children are even rarer than in adults, but in similar fashion to the other neurobiological measures described, results thus far have both agreed with and contradicted findings in adults. Steingard et al. (1996) performed a retrospective chart review and reanalysis of clinical MRIs obtained from 65 children with Major Depressive Disorder, compared with 8 nondepressed psychiatric controls. Findings included a smaller ratio of the frontal lobe to total cerebral volume and a larger ratio of the

ventricles to total cerebral volume, consistent with findings of decreased frontal lobe volume in adults. Botteron and colleagues (Botteron, Raichle, Drevets, Heath, & Todd, 2002) followed up the findings of significantly decreased subgenual prefrontal cortex volume in adults with mood disorders to determine whether there was an age-related effect. They compared females with early-onset depression (average age 20.2 \pm 1.6 years) with later-onset depression (35.8 \pm 8.1) and two groups of appropriately age-matched controls, and found that although the left subgenual prefrontal cortex was smaller in both patient groups, there did not appear to be any difference according to age of onset of symptoms.

Nolan et al. (2002) focused on psychotropic-naïve children and adolescents to minimize the potential confounding effects of medication. They compared subjects with and without a familial history of depressive disorder and found larger prefrontal cortex volumes of gray and white matter on the left side in the nonfamilial cases only. This finding was different from the smaller prefrontal volumes typically reported in adults, although the small sample size merits caution.

Three studies have reported on temporal lobe structures. MacMillan et al. (2003) studied psychotropic-naïve subjects and reported that the ratio of the volumes of the amygdala to the hippocampus was increased on the left side, although the difference in amygdala or hippocampal volumes were not statistically significant after controlling for intracranial volume and age. MacMaster and Kusumakar (2004) found decreased hippocampal volume (17%) in a group with mixed exposure to medications, again localized to the left. Findings persisted when they examined only the psychotropic-naïve subgroup. They also reported a positive correlation between hippocampal size and duration of illness and a negative correlation with age of onset. Rosso et al. (2005) examined amygdala and hippocampal volumes in a slightly larger group of primarily females. They found both the left and right amygdala to be an average of 12% smaller in patients, but did not find a difference in hippocampal volumes or total cerebral volume.

Conclusion. Although conclusions that can be drawn from the neuroimaging literature are limited by small sample sizes and varying methodologies, there is evidence to support the presence of structural brain differences in regions known to be involved in emotional regulation, including the frontal cortex, temporal lobe structures, basal ganglia, and cerebellar vermis. All studies to date have been cross-sectional, meaning that firm conclusions cannot be drawn about the relative trajectories of brain volume changes in early- versus adult-onset depression (Kraemer et al., 2000). Nonetheless, the appearance of volumetric differences in prefrontal cortex and basal ganglia in younger populations suggests that these may be features either related to vulnerability to mood disorder or that occur early on, whereas the findings of normal hippocampal morphology in children and adolescents contrasts with the smaller volumes seen in adults.

The findings of specific rather than generalized structural differences, with clearer effects when examined in smaller regions such as the subgenual prefrontal cortex SGPFC and cerebellar vermis, indicate that approaches parcellating the brain into smaller and more functionally relevant regions may be more fruitful. In addition, the recent advances in MRI techniques such as DTI that allow more informative descriptions of white matter structure may help to elucidate the role of robust findings such as increased WMH in both children and adults with mood disorders.

A potential confounding factor that is beginning to receive more attention is the impact of medications on brain structural measures. Although it has been recognized for some time in the Schizophrenia literature that many an-

tippsychotics can affect brain structural measures (Chakos et al., 1994; Elkashef et al., 1994; Keshavan et al., 1994), there has been less attempt to account for this in the study of affective disorders, despite the frequent use of antipsychotic medications both for mood-related psychotic symptoms and as primary mood-stabilizing agents.

There is also evidence to support that the classic mood stabilizers may also affect brain structure. Findings in animal models that lithium and valproic acid may have neuroprotective effects have generated considerable interest (Manji, Moore, Rajkowska, & Chen, 2000), and three studies in humans have found brain structural correlations with lithium exposure. A study of subgenual prefrontal cortex by Drevets et al. (1997) looked at volume loss in regard to exposure to lithium and found that the subgroup that had been treated with lithium or valproic acid did not show the same cortical loss. A longitudinal study by the same group found significant increase in gray matter volume in 8 out of 10 patients with Bipolar Disorder following a 4-week trial of lithium treatment (G. J. Moore, Bebchuk, Wilds, Chen, & Manji, 2000). An independent study of anterior cingulate volume in adults with Bipolar Disorder found that treatment-naïve patients had reduced anterior cingulate volumes, whereas volumes in lithium-treated patients were not different from controls (Sassi et al., 2004).

The relationship of these findings to the pathophysiology of mood disorders and neurodevelopmental processes will benefit from the application of study designs similar to those being increasingly used in the more mature Schizophrenia literature, including exploration of state/trait differences through study of high-risk populations and longitudinal studies beginning early in the course of the disorder. Also similarly to Schizophrenia, the considerable heterogeneity of mood disorders may be more easily related to genetic vulnerabilities through the identification of particular structural or physiological characteristics which can be used as endophenotypes (Almasy & Blangero, 2001; Gottesman & Gould, 2003). Neurophysiological differences between children and adults will also be important to consider further in order to understand why children do not appear to show the same hippocampal abnormalities as seen in adults, similarly to the findings previously described in PTSD. One of the current theories regarding the pathogenesis of the hippocampal findings in depression in adults is a neurotoxic effect of hypercortisolemia (Rajkowska, 2003). As cortisol responses to stress appear to differ in children, prospective longitudinal studies extending from childhood into adulthood will be necessary to determine whether these inconsistencies in imaging findings are due to heterogeneous subtypes of the disorder or are developmental in nature.

SUMMARY AND FUTURE DIRECTIONS

In the past 25 years, neuroimaging techniques have become an essential tool in the study of normal and abnormal neurodevelopment. MRI in particular has provided the ability to include repeated direct *in vivo* measurements of brain structures throughout the life span, bringing into view a new level of biological organization. The newfound accessibility of brain structure measures as quantifiable phenotypes has made possible a much richer integration of human neurodevelopment and psychology within the broader field of developmental biology.

Since the first CT pictures of enlarged ventricles in individuals with Schizophrenia (Johnstone et al., 1976), neuroimaging has provided concrete evidence that psychiatric disorders are based in the brain. However, the nature of the relationship between brain structure and many brain functions is still poorly understood. For example, as of this writing, neuroimaging investigations of the childhood-onset neuropsychiatric disorders described in this chapter are not of diagnostic utility except to rule out possible central nervous system insults such as tumors, intracranial bleeds, and congenital anomalies as etiologies for the symptoms. There is no identified “lesion” common to all, or even most, children with disorders such as Autism, ADHD, Schizophrenia, dyslexia, juvenile-onset bipolar disorder, depression, PTSD, or OCD. There is enormous variation in brain structural findings even in the disorders with known genetic etiologies such as Fragile X disorder or Rett syndrome.

Attempts to link brain structure and functional capacities such as IQ are also not straightforward. As seen in the section on normal development, similar functional capacity can be found in boys of similar age but with brain volumes differing by as much as 40% (Giedd, 1996). Similarly, boys consistently have larger brain volume than girls, yet there is not a significant difference in IQ (Giedd, 1996). An individual can sustain surprisingly large amounts of damage to some parts of the brain without permanent loss of function if injury occurs sufficiently early in life (Anderson, Damasio, Tranel, & Damasio, 2000; Kennard, 1940).

Nonetheless, correlations have been identified between some aspects of brain structure and functional capacity. Several studies have shown that there are correlations of brain structural measures with IQ on both whole-brain and regional levels (Haier, Jung, Yeo, Head, & Alkire, 2004; Posthuma et al., 2002; Thompson, Cannon, et al., 2001; Toga & Thompson, 2004). Relationships between memory function and hippocampal size have also been noted in several species. Food-storing species of birds have larger hippocampi than related non-food-storing species

(Krebs, Sherry, Healy, Perry, & Vaccarino, 1989; Sherry, Vaccarino, Buckenham, & Herz, 1989), and in mammals, a similar example can be found in voles. Male voles of the polygamous species travel far and wide in search of mates; they perform better than their female counterparts on laboratory measures of spatial ability and have significantly larger hippocampi (Sherry, Jacobs, & Gaulin, 1992). Conversely, in the monogamous vole species, which do not show male-female differences in spatial ability, no sexual dimorphism of hippocampal size is seen (Jacobs, Gaulin, Sherry, & Hoffman, 1990). In humans also, correlations between memory for stories and left hippocampal volume have been noted (Goldberg, Torrey, Berman, & Weinberger, 1994; Lencz et al., 1992). A study of taxi drivers in London found that they had larger hippocampi than controls, thought to be related to their extensive amount of navigational memory required for their work (Maguire et al., 2000).

Some general impressions can be drawn from findings in neurodevelopmental disorders as well. The very early onset disorders such as Fragile X and Autism tend to have diffuse effects. In the absence of longitudinal studies, it is not known whether these are progressive. Disorders with onset during later childhood, such as OCD and ADHD, appear to show more focal structural changes. These are also relatively static compared to disorders with a marked loss of function such as Schizophrenia, which are characterized by a progressive loss of brain tissue. Rett syndrome might be expected to show a similar progressive loss of tissue during stages of the illness in which clinical deterioration is occurring, but at this time there are no longitudinal reports with which to determine if this is the case. Structural changes in mood disorders and PTSD have been less clear but have shown an intriguing relationship between developmental onset of illness and the nature of associated brain changes, in that children with depression and PTSD have not been found to have the smaller hippocampal volumes seen in adults.

The studies reviewed in this chapter, as well as the many not included here, have provided the essential first explorations of what this new tool can contribute to our understanding of typical and atypical development. It will not have escaped the reader that the findings thus far in many childhood-onset psychiatric disorders have been both inconsistent and nonspecific. As mentioned earlier, many of the inconsistencies may be attributed to methodological issues. To some extent, the lack of specificity is also not unexpected—using any phenotypic measure well, including one such as brain morphometry, involves knowing its variability and how it is impacted by factors such as age, sex, and environment (Vitzthum, 2003). The neuroimaging

studies obtained to date are just starting to provide descriptions of some of these features, and the degree to which the brain shows structural differences due to these is turning out to be more significant than perhaps expected.

The realization of how much plasticity can be exhibited in even the adult brain has also begun to hint at how complex the relationship is between brain structure and development. As articulated by several investigators (Ansari & Karmiloff-Smith, 2002; Cicchetti & Cohen, 1995; Gottlieb & Halpern, 2002; M. H. Johnson, Halit, Grice, & Karmiloff-Smith, 2002; Karmiloff-Smith et al., 2004; Peterson, 2003; Rutter & Sroufe, 2000; Sameroff & Mackenzie, 2003; Thomas & Karmiloff-Smith, 2002), the structure of the brain at any time is a product of a complex interaction among genetic, epigenetic, and environmental factors ("environmental" taken broadly as including both the outside environment and the internal physiological milieu). Stresses placed on the developing individual by a mismatch between his or her capacities and demands placed by the environment will result in compensatory physiological responses and behaviors that in time may affect brain structures. Within limits this is a description of the normal learning process. However, if the mismatch is severe, this process can result in pathology, particularly if compensations result in further pathology directly or through triggering adverse environmental reactions such as increased familial stress. It is not possible to determine *ex post facto* from a neuroimaging study which features are related to the initial perturbation or genetic anomaly and which to downstream effects—the "inverse solution" problem, as reviewed by Courchesne et al. (1995). Longitudinal studies beginning as early as possible are the best means to try to tease apart how brain structure relates to other factors affecting the developmental trajectory (Peterson, 2003). Such studies are unfortunately difficult to perform due to logistical issues, but, as described previously, the few available to date have been fruitful in showing significant differences in trajectories that were not apparent from previous cross-sectional studies (Giedd, Blumenthal, et al., 1999; Gogtay, Giedd, et al., 2004).

Another crucial issue for neuroimaging studies of brain development is the selection of the groups to be studied. One of the basic principles from developmental biology is that of equifinality, meaning that a given phenotype can be arrived at through many paths. In the realm of neuropsychiatric disorders, the diagnostic categories are just such phenotypes. It has become increasingly clear that the diagnostic categories most frequently used in clinical practice are not necessarily the most informative for correlation with biological measures such as brain structures. The

DSM-IV states in its introduction that its diagnostic syndromes were not based strictly on biological criteria (which are not available for most psychiatric disorders), but were arrived at through balancing a variety of concerns, including historical tradition, compatibility with the *International Classification of Diseases 10*, clinical and research data, and consensus of experts in the field (American Psychiatric Association, Task Force on *DSM-IV*, 2000). In addition, the use of polythetic criteria within a categorical classification system as seen in the *DSM-IV* predisposes toward heterogeneity of individuals within a diagnostic category.

Approaches to diminish heterogeneity include identifying more homogeneous diagnostic subtypes, such as the deficit syndrome in Schizophrenia, and scoring individual symptoms on dimensional scales and clustering individuals accordingly. Both of these may be helpful in some settings, but do not necessarily have a clearer relationship to any particular biologically meaningful measure. The identification of endophenotypes is a different strategy that has been gaining attention in the study of psychiatric disorders in recent years. These are heritable traits related to the disease pathology, not due to treatment or disease-induced degeneration, and which are found in milder form in family members without the full-blown syndrome. Current examples in Schizophrenia include eye-tracking abnormalities (Calkins & Iacono, 2000; Holzman et al., 1974) and deficits in P50 suppression (Braff & Freedman, 2002; Braff, Geyer, & Swerdlow, 2001). It is theorized that these traits, being simpler than the full version of disorder, will be associated with a smaller and more easily identified set of genes (Gottesman & Gould, 2003). They also may provide a means to introduce a biologically or genetically based element into the classification of psychiatric disorders to increase the reliability and validity of psychiatric diagnoses and the likelihood of finding meaningful associations with other biological measures. Brain imaging studies organized by biologically based endophenotypes may suffer less from noise introduced by diagnostic heterogeneity. In addition, brain structural measures themselves are capturing increased attention as potential endophenotypes.

Attention to reliable and consistent diagnostic criteria gains additional importance from the current efforts to implement multicenter imaging studies; several of these are currently in process in different regions around the world. Such studies will provide an invaluable means of obtaining sufficient statistical power to address the interactions of genes and environmental factors on brain structure and function on a population level. The impact of environmental factors in particular has been understudied in neuroimaging research, an aspect that will need to be addressed if accurate representations of the relationship between genetic charac-

teristics and outcome are to be obtained (Vineis, 2004). The additional challenges posed by attempting to match diagnostic criteria and imaging methods between different areas and even different countries will be important to consider in the design and interpretation of such studies. The development of quantitative imaging methods that are not scanner-dependent and automated image analysis methods will be particularly valuable in making it possible to combine large amounts of data between sites.

The nature of the neuroimaging measures obtained is another important methodological issue affecting specificity of findings. The measures reported for most neuroimaging studies thus far has been at the level of whole-brain and lobar volumes, which are too gross to be informative about specific functionally relevant neuroanatomic circuits. Higher field scanners and advances in acquisition techniques are making possible very high resolution that allows accurate delineation of much smaller and potentially more functionally meaningful anatomic regions.

At least equally important is the evolution of analytic techniques through concurrent progress in computational power and increasingly sophisticated statistical modeling. This is making possible the comparison of brain structural measures between groups on much finer levels, including sulcal parcellations and cluster analysis on a voxel-by-voxel basis (see Figure 3.10) (Thompson et al., 1997, 2004).

Different levels of brain organization and function are described by the many disciplines that touch on this field. To integrate these, there is a need for more studies that combine structural neuroimaging with measures from other levels of biological complexity such as genes or behavior (Toga & Mazziotta, 2002; Toga & Thompson, 2004). For example, the question regarding the relative contributions of increased myelination versus pruning to the observed loss of cortical gray matter during adolescent brain development (Sowell, Thompson, et al., 2001) will most likely benefit from using methods such as magnetization transfer that are affected by macromolecular concentrations and thus provide information about whether concentrations of myelin are increasing. Such correlations will also require increased efforts to determine the precise sources of the signals observed in structural neuroimaging studies through imaging combined with postmortem validation in animal models.

As the chief purpose of studies of brain structure is to better understand cognition and behavior, the integration of structural and functional measures is particularly important. Functional neuroimaging provides the ability to see changes in brain activity as they relate to real-time thoughts and behaviors. The plasticity of the brain in response to use implies that abnormal functional patterns may eventually be reflected in an alteration of the trajectory of brain structural

Figure 3.10 Right lateral and top views of the dynamic sequence of gray matter maturation over the cortical surface. The side bar shows a grey scale representation in units of GM volume.

development, but longitudinal studies using a combination of functional and structural modalities are necessary to determine to what extent this is actually the case (Nagy, Westerberg, & Klingberg, 2004). Along the same lines, only multimodal imaging will be able to address questions of brain function as it relates to connectivity of different brain regions. An ongoing question for fMRI studies is how the different areas of activation actually relate to each other. Being able to determine whether activated areas are parts of the same neuroanatomic circuit, and to assess the integrity of that circuit, will provide the necessary link between functional patterns, their physical foundation, and the features on the cellular, synaptic, and genetic levels that may impact them (Ramnani, Behrens, Penny, & Matthews, 2004).

Finally, to return to the statements that began this chapter, the ability to create images of the living brain has generated tremendous excitement in the scientific and lay communities. Although the initial stages of determining the capabilities of a new method like structural neuroimaging are of necessity exploratory, like any other technique neuroimaging must eventually take its place as one tool among many to address specific hypotheses arising from a clearly articulated theoretical foundation. This is particularly important for two reasons in the case of neuroimaging studies of brain development. One is the complexity of the multiple layers of potentially interacting factors and the impossibility of relating them accurately or intelligibly without a strong theoretical framework to guide interpretation. The second is the rhetorical impact of findings from neuroimaging studies. The “seeing is believing” aspect of neuroimaging studies can seem to offer the promise of concrete, objective answers to long-standing and vexatious issues, such as when adolescents have the capacity to be held responsible for their own actions. However, the relatively early stages of our ability to relate brain structural features to particular causative pathways of normal or abnormal development means that, at this point, specific findings should not be interpreted as more than indicators of potential risk factors for abnormal functioning that must be placed in the context of clinical status and as clues to the developmental processes that may be at work.

Until recently, the postnatal development of human psychological functions was studied independently of their underlying neural substrates. Developmental psychologists used measures of behavior to assess theories of cognitive, perceptual, and linguistic development; developmental neuroscientists investigated detailed changes in brain structure and chemistry in humans and other species. Although occasional attempts were made to relate these two fields, only in the past decade has the hybrid field known as “developmental cognitive neuroscience” (Johnson, 2005) emerged. In assessing the progress made to date, it is interesting to note that three main approaches, each with different sets of underlying assumptions, have been taken. In this chapter, we outline these three perspectives on human functional brain development before assessing their application and different implications for understanding empirical evidence from (1) functional brain imaging, (2) the effects of early acquired brain damage, and (3) the consequences of atypical early experience.

THREE PERSPECTIVES ON THE FUNCTIONAL DEVELOPMENT OF THE HUMAN BRAIN

Relating evidence on the neuroanatomical development of the brain to the remarkable changes in motor, perceptual, and cognitive abilities during the 1st decade or so of human life presents a considerable challenge. We have identified three distinct, but not necessarily incompatible, approaches to this issue: (1) a maturational viewpoint, (2) interactive specialization, and (3) a skill-learning viewpoint. We briefly introduce these three approaches, before going on to examine their assumptions and predictions in more detail.

Maturational Viewpoint

According to the maturational viewpoint, newly emerging sensory, motor, and cognitive functions are related to the maturation of particular areas of the brain, usually regions

of cerebral cortex (Figure 4.1a). Much of the research to date attempting to relate brain to behavioral development in humans has taken this approach. Evidence concerning the differential neuroanatomical development of brain regions should then predict the age when a particular region is likely to become functional. Conversely, success in a new behavioral task at a given age is attributed to the maturation of a new brain region. For example, some investigators have suggested that the development into adolescence of the ability to detect error-related conflict in action-monitoring tasks is linked to maturation of the anterior cingulate cortex (Ladouceur, Dahl, & Carter, 2004). Functional brain development is in this sense depicted as the reverse of adult neuropsychological studies of patients with brain damage, with specific brain regions being added in during development instead of being “subtracted” by damage.

Despite the intuitive appeal and attractive simplicity of the maturational approach, it does not successfully explain all aspects of human functional brain development. One aspect that is difficult to account for in this view is that some of the cortical regions that are slowest to develop by neuroanatomical criteria show activity from shortly after birth and appear to mediate cognitive functions even before they would be considered anatomically fully mature. For example, the prefrontal cortex continues to mature into the teenage years according to neuroanatomical criteria, but functional imaging studies show evidence that it can be activated during the first months (see Johnson, 2005, for review). Thus, the emergence of new behaviors is not necessarily linked to a previously immature, silent neural region becoming active when it matures. In fact, where functional activity has been assessed by functional magnetic resonance imaging (fMRI) during a behavioral transition, multiple cortical and subcortical areas appear to change their response pattern (Luna et al., 2001) rather than a few specific areas becoming active. Another difficulty for the maturational viewpoint is that associations between neural and cognitive changes based on age of onset are theoretically weak due to the great variety of neuroanatomical and neurochemical measures that change at different times in different regions of the brain. Thus, it is nearly always possible to find a potential neural correlate for any behavioral change.

Interactive Specialization

In contrast to the maturational viewpoint, the interactive specialization viewpoint assumes that postnatal functional brain development, at least in the cerebral cortex, involves a process of organizing patterns of interregional interac-

Figure 4.1 A hypothetical illustration of three accounts of the neural basis of an advance in behavioral abilities in infants. Panel A represents a maturational view in which maturation of one region (in this case, the dorsolateral prefrontal cortex) enables new behavioral abilities to appear. Panel B illustrates an interactive specialization view in which the onset of a new behavioral ability is due to changes in the interactions between regions that were already partially active. By this view, several regions adjust their functionality together to enable new computations. Panel C shows a third perspective, skill learning, in which certain regions become active during the acquisition of a range of new skills throughout the life span. The activation of some of these skill acquisition regions declines as expertise is developed. Thus, in some simple visuomotor tasks, infants will have more regions activated than older children and adults. These three accounts are not mutually exclusive. *Source:* From “Functional Brain Development in Humans,” by M. H. Johnson, 2001, *Nature Reviews Neuroscience*, 2, pp. 475–483. Reprinted with permission. (www.nature.com)

tions (Johnson, 2000; Figure 4.1b). According to this view, the response properties of a specific brain region are partly determined by its patterns of connectivity to other regions, and their patterns of activity. During postnatal development, changes in the response properties of cortical regions occur as they interact and compete with each other to acquire their role in new computational abilities. From this perspective, some cortical regions may begin with poorly defined, general-purpose functions and consequently are partially activated in a wide range of different contexts and tasks. During development, activity-dependent interactions between regions sharpens up their functions such that their activity becomes restricted to a narrower set of circumstances (e.g., a region originally activated by a wide variety of visual objects may come to confine its response to upright human faces). The onset of new behavioral competencies during infancy will therefore be associated with changes in activity over several regions, and not just by the onset of activity in one or more additional regions.

Skill Learning

A third perspective on human functional brain development, skill learning, involves the proposal that the brain regions active in infants during the onset of new perceptual or motor abilities are similar or identical to those involved in complex skill acquisition in adults (Figure 4.1c). For example, Gauthier and colleagues (Gauthier, Tarr, Anderson, Skudlarski, & Gore, 1999) have shown that extensive training of adults to identify individual artificial objects (called “greebles”) eventually results in activation of a cortical region previously preferentially activated by faces, the fusiform face area. This suggests that the region is normally activated by faces in adults, not because it is prespecified to do so, but due to our extensive expertise with that class of stimulus. Extended to ontogeny, this view would argue that development of face processing during infancy and childhood could proceed in a manner similar to acquisition of perceptual expertise for a novel visual category in adults

(see Gauthier & Nelson, 2001). Although the degree to which parallels can be drawn between adult expertise and infant development remain unclear, to the extent that the skill-learning hypothesis is correct, it presents a clear view of a continuity of mechanisms throughout the life span.

ASSUMPTIONS UNDERLYING THE THREE APPROACHES

Table 4.1 illustrates some of the assumptions that underlie the three approaches we have outlined.

Deterministic versus Probabilistic Epigenesis

Gottlieb (1992) distinguished between two approaches to the study of development: *deterministic epigenesis*, in which it is assumed that there is a unidirectional causal path from genes to structural brain changes to psychological function, and *probabilistic epigenesis*, in which interactions among genes, structural brain changes, and psychological function are viewed as bidirectional, dynamic, and emergent. In many ways, it is a defining feature of the maturational approach that it assumes deterministic epigenesis; region-specific gene expression is assumed to effect changes in intraregional connectivity that, in turn, allow new functions to emerge. A related assumption commonly made in the maturational approach is that there is a one-to-one mapping between brain and cortical regions and particular cognitive functions, such that specific computations come online following that maturation of circuitry intrinsic to the corresponding cortical region. In some respects, this view parallels mosaic development at the cellular level, in which simple organisms (such as *C. Elegans*) are constructed through cell lineages that are largely independent of each other (Elman et al., 1996). Similarly, different cortical regions are assumed to have different maturational timetables, thus enabling new cognitive functions to emerge at different ages.

TABLE 4.1 Assumptions Underlying the Three Approaches to Functional Brain Development

	Brain-Cognitive Mapping	Primary Locale of Changes	Plasticity	Cause
Maturational	One-to-one mapping. Static over development.	Intraregion connectivity matures.	A specialized mechanism invoked by stroke or injury.	Brain changes cause cognitive development.
Skill-learning	Changes during acquisition of skill.		Lifelong; no clear sensitive period.	
Interactive	Networks/neural systems. Dynamic changes during development.	Interregional connectivity changes and shapes intraregional connectivity.	An inherent property: the state of having not yet specialized. Sensitive: period determined by state of specialization.	Bidirectional relations between structure and function.

In contrast to the maturational approach, interactive specialization (IS; Johnson, 2000, 2001, 2005) has a number of different underlying assumptions. Specifically, a probabilistic epigenesis assumption is coupled with the view that cognitive functions are the emergent product of interactions between different brain regions. In this respect, IS follows views in adult functional neuroimaging. For example, Friston and Price (2001) point out that it may be an error to assume that particular functions can be localized in a certain cortical region. Rather, they suggest that the response properties of a region are determined by its patterns of connectivity to other regions as well as by their current activity states. In this view, “The cortical infrastructure supporting a single function may involve many specialized areas whose union is mediated by the functional integration among them” (pp. 276). Similarly, in discussing the design and interpretation of adult fMRI studies, Carpenter and collaborators (2001, pp. 360) have argued:

In contrast to a localist assumption of a one-to-one mapping between cortical regions and cognitive operations, an alternative view is that cognitive task performance is subserved by large-scale cortical networks that consist of spatially separate computational components, each with its own set of relative specializations, that collaborate extensively to accomplish cognitive functions.

Extending these ideas to development, the IS approach emphasizes changes in interregional connectivity, as opposed to the maturation of intraregional connectivity. Whereas the maturational approach may be analogous to mosaic cellular development, the IS view corresponds to the regulatory development seen in higher organisms in which cell-cell interactions are critical in determining developmental fate. Mosaic development can be faster than regulatory, but the latter has several advantages; namely, regulatory development is more flexible and better able to respond to damage, and it is more efficient in terms of genetic coding. In regulatory development, genes need orchestrate only cellular-level interactions to yield more complex structures (see Elman et al., 1996).

Static versus Dynamic Mapping

As well as the mapping between structure and function at one age, we can also consider how this mapping might change during development. When discussing functional imaging of developmental disorders, Johnson, Halit, Grice, and Karmiloff-Smith (2002) point out that many investigators have assumed that the relation between brain structure

and cognitive function is unchanging during development. Specifically, in accordance with a maturational view, these researchers believe that when new structures come online, the existing (already mature) regions continue to support the same functions they did at earlier developmental stages. The “static assumption” is partly why it is acceptable to study developmental disorders in adulthood and then extrapolate back in time to early development. Contrary to this view, the IS approach as expounded by Johnson and colleagues (Johnson, 2001; Johnson et al., 2002) suggests that when a new computation or skill is acquired, there is a reorganization of interactions between different brain structures and regions. This reorganization process could even change how previously acquired cognitive functions are represented in the brain. Thus, the same behavior could be supported by different neural networks at different ages during development. For example, adult monkeys with lesions to the medial temporal lobe or inferior prefrontal convexity show marked impairments in rule learning in the delayed nonmatching-to-sample task (DNMS task; Meunier, Bachevalier, & Mishkin, 1997), indicating that both areas are key components in the neural network supporting performance on the task. By contrast, monkeys with neonatal lesions to the medial temporal lobes show similar impairments at 3 months and 2 years of age, but with inferior convexity lesions show no impairments at 3 months and only very mild ones at 2 years (Malkova, Bachevalier, Webster, & Mishkin, 2000). The authors interpret these results as showing learning of the response rule in the DNMS task depends mainly on the medial temporal lobe in young monkeys, whereas at later ages it requires functional interactions between the medial temporal lobe and inferior frontal cortex.

Stating that structure-function relations can change with development is all very well, but it lacks the specificity required to make all but the most general predictions. Fortunately, the view that there is competitive specialization of regions during development gives rise to expectations about the types of changes in structure-function relations that should be observed. Specifically, as regions become increasingly selective in their response properties during infancy, patterns of cortical activation during behavioral tasks may therefore be more extensive than those observed in adults and involve different patterns of activation. Additionally, within broad constraints, successful behavior in the same tasks can be supported by different patterns of cortical activation in infants and adults. Evidence in support of this view is discussed later in the chapter.

The basic assumption underlying the skill-learning approach is that there is a continuity of the circuitry underlying

ing skill acquisition from birth through to adulthood (for review of the neural systems involved in perceptual and motor skill learning in adults, see Poldrack, 2002; Ungerleider, Doyon, & Karni, 2002). These circuits are likely to involve a network of structures that retains the same basic function across developmental time (a static brain-cognition mapping). However, other brain regions may respond to learning with dynamic changes in functionality similar or identical to those hypothesized in the IS framework. For example, neuroimaging studies of adults acquiring the skill of mirror reading show both increases and decreases of cortical activity over widespread regions during learning: Unskilled performance is associated with activation in bilateral occipital, parietal, and temporal lobes and the cerebellum, with acquisition of skill leading to decreases in bilateral occipital and right parietal activation and to increased inferior temporal lobe and caudate nucleus activation (Poldrack, Desmond, Clover, & Gabrieli, 1998; Poldrack & Gabrieli, 2001). According to the skill-learning view, similar dynamic changes in brain activation would occur as skills emerge during development.

Plasticity

Another way the three perspectives differ is with regard to plasticity. Plasticity in brain development is a phenomenon that has generated much controversy, with several different conceptions and definitions having been presented. According to the maturational framework, plasticity is a specialized mechanism that is activated following brain injury. According to the IS approach, plasticity is simply the state of a region's function being not yet fully specialized; that is,

there is still scope for developing more finely tuned responses. In this view, the mechanisms of plasticity remain the same throughout the life span, but the expression of plasticity is more limited in adulthood because many regions of the brain have already become specialized and there is less scope for further change. This definition corresponds well with the view of developmental biologists that development involves the increasing "restriction of fate." Finally, according to the skill-learning hypothesis view, the functional plasticity present in early development may share many characteristics with the plasticity underlying acquisition and retention of skills in adults (Karni & Bertini, 1997). The key difference from the IS approach is that in the skill-learning view, plasticity does not necessarily reduce during development (for a more detailed discussion of critical/sensitive periods for plasticity in development, see predictions for effects of brain injury and atypical experience, discussed later).

PREDICTIONS OF THE THREE APPROACHES

Some predictions of the three approaches are given in Table 4.2. Before we assess areas of empirical data in detail, we review the types of predictions that arise from the three approaches. The first set of predictions concerns the neural correlates of the onset of new abilities during development. According to a maturational view, new behavioral abilities are mediated by new components of cognition that are, in turn, allowed by the maturation of one or more brain regions. A consequence of this is a general increase in the number of structures that can be activated in tasks with

TABLE 4.2 Predictions of the Three Approaches to Functional Brain Development

	Brain Imaging 1	Brain Imaging 2	Effects of Acquired Damage	Effects of Atypical Early Experience
Maturational	New skills associated with onset of functional activity in one or more regions. An increasing number of regions active with age.	Specific regions activated by particular functions throughout development.	Need to infer specialized mechanisms of plasticity and give separate explanation for sensitive periods.	Experience accelerates or decelerates rates of maturation.
Skill learning	New skills associated with activation of skill-learning circuit. Changes in cortical activation with experience.	Skill learning of networks achieved at task onset, with other regions taking over as skill is acquired.	Damage to skill learning circuit has long-lasting and widespread effect. Otherwise, same degree of plasticity as in adults.	Effects of early deprivation are reversible because same mechanisms of skill acquisition are available in later life.
Interactive	New skills associated with changing activation of widespread network of regions. Extent of cortical activation could decrease with age.	Regions become more fine-tuned/specialized in their response properties with development.	Remaining regions can specialize in other ways to compensate for loss. When regions are specialized, plasticity terminates.	Atypical early experience may set up atypical patterns of regional specialization.

development. In contrast to these predictions, in the IS approach it is anticipated that widespread networks of brain regions will change their patterns of activation in association with the onset of new behavioral abilities. In addition, regions will become more specialized (finely tuned) in their response properties with experience. A consequence of this specialization is that, on at least some occasions, fewer brain regions are activated with development in certain tasks. Turning to the skill-learning approach, here we anticipate that the onset of new abilities will often be associated with activation of a network of skill acquisition areas. As the new behavioral ability is acquired, a different network of brain regions may become involved.

With regard to the issue of how functions are mapped onto patterns of brain activity, according to the maturational approach, if we compare two age groups in a task for which they show identical behavioral performance, we should also expect to see identical patterns of brain activation. This is not necessarily the case for the IS approach, because the exact patterns of brain activation that support a function will change according to the degree of specialization of component regions within the supporting network. Indeed, the IS approach predicts that the patterns of regional brain activation supporting a function will change during development. Although the exact nature of this change will depend on the degree of specialization achieved in different component structures, the IS view predicts a general trend for a decrease in the extent of cortical activation with increasing development/experience. The skill-learning view invokes the reactivation of one or more skill-learning circuits at the onset of a task, followed by a different pattern of activation after the skill is acquired. In this case, in many comparisons between age groups, the younger group will have acquired the skill in less depth than the older group, giving rise to different patterns of underlying brain activation. Interestingly, however, patterns of changing brain activation while adults acquire new skills should mirror the changes seen during development as infants and children acquire simpler skills.

The three perspectives yield different types of predictions about the consequences of perinatal brain damage. According to the maturational view, additional mechanisms of plasticity are activated following early damage. Specific additional explanations are then required to account for incidents of recovery of function. Also, it is not obvious why the extent of plasticity is greater earlier in life. From the IS perspective, there is a parsimonious explanation of recovery of function following perinatal damage, as the regional specialization of the remaining brain regions will be altered to compensate, particularly the corresponding regions in the other hemisphere. In cases of bi-

lateral or extensive damage, recovery is less likely. From the skill-learning perspective, plasticity is a lifelong feature of the brain. Damage to the general circuits critical for skill acquisition will have long-lasting and widespread consequences, and damage to circuits specific to acquisition of particular skills or their retention may result in more isolated impairments. Of the three approaches, IS gives the simplest account of sensitive periods for plasticity, as plasticity is reduced when specialization of corresponding regions is achieved.

With regard to the long-term effects of atypical early experience, or even variations of experience within the normal range, once again the three frameworks lead to different sets of expectations. From the skill-learning perspective, variations in early experience will determine the extent of skills acquired. Early deprivation will be potentially reversible because the same mechanisms of skill acquisition are available later in life. From the IS perspective, long-term effects of atypical early experience can result from atypical patterns of regional specialization arising early in life. Such atypical patterns of specialization may be difficult to reverse once established. Finally, under the maturational view, a primary variable influenced by the environment is the speed of maturation that may affect the level or maintenance of a skill. It is sometimes argued that early sensory deprivation may have a general slowing effect on the sequence of maturation.

BRAIN IMAGING OF TYPICAL DEVELOPMENT

In this section, we review evidence from the functional neuroimaging of normal development that pertains to the three perspectives on functional brain development. We argue that the majority of evidence currently available does not offer much support to the maturational view. Instead, behavioral change seems to be accompanied by large-scale dynamic changes in the interactions between regions, and different cortical regions become more specialized for functions as a consequence of development.

A maturational approach to human postnatal functional brain development predicts that a neural correlate of increasing behavioral abilities is an increasing number of active cortical areas. In functional imaging paradigms, therefore, infants and children should show less active regions in tasks where they show poorer behavioral performance than do adults. In contrast, if new behaviors require changes in interregional interaction, the IS view predicts a greater or equal extent of cortical activation and may find

different patterns of activation early in development even in task domains where behavioral performance is similar to that of adults. Comparing activation in cases where behavioral performance is equated is critical for distinguishing the IS view from both the skill-learning view and the maturational view, as only the former predicts that the pattern of brain activation may differ with age even when performance is equated. Which of these approaches is adopted has not only theoretical implications but also practical implications for data collection. For example, if one adopts the maturational approach and is expecting a particular area to become active during development for a particular task, then brain imaging may be focused on that region rather than on the whole brain. As a consequence, any possible changes in more distant brain structures would not be detected. By contrast, if one adopts the IS approach, the importance of whole-brain imaging is clearly apparent.

A number of authors have described developmental changes in the spatial extent of cortical activation in a given situation during postnatal life. Event-related potential (ERP) experiments with infants have indicated that both for word learning (Neville, Mills, & Lawson, 1992) and face processing (de Haan, Pascalis, & Johnson, 2002) there is increasing localization of processing with age and experience of a stimulus class. That is, scalp recording leads reveal a wider area of processing for words and faces in younger infants than in older ones whose processing has become more specialized and localized. In the IS framework, such developmental changes are accounted for in terms of more pathways being partially activated in younger infants prior to experience with a class of stimuli. With increasing experience, the specialization of one or more of those pathways occurs over time. Taking the example of face processing, in early infancy both the left and the right ventral visual pathways are differentially activated by faces, but in many (although not all) adults, face processing localizes largely to the right ventral pathway (Johnson & de Haan, 2001). In the example of word recognition, ERP activity differentiating between comprehended and noncomprehended words is initially found over widespread cortical areas. This narrows to left temporal leads after children's vocabularies have reached a certain level, irrespective of maturational age (Mills, Coffey, & Neville, 1993). Changes in the extent of localization can be viewed as a direct consequence of specialization. Initially, multiple pathways are activated for most stimuli. With increasing experience, fewer pathways become activated by each specific class of stimuli. Pathways become tuned to specific functions and are therefore no longer engaged by the broad range of stimuli, as was the case earlier in development. Additionally,

there may be inhibition from pathways that are becoming increasingly specialized for that function. In this sense, there is competition between pathways to recruit functions, with the pathway best suited for the function (by virtue of its initial biases) usually winning out.

Further evidence to support the IS view comes from recent fMRI studies in children. Luna and colleagues (2001) tested participants age 8 to 30 years in an oculomotor response-suppression task. Their behavioral results showed that the adult level of ability to inhibit prepotent responses developed gradually through childhood and adolescence. The difference between prosaccade and antisaccade conditions was investigated with fMRI and revealed changing patterns of brain activation during development. Both children and adolescents had less activation than adults in a few cortical areas (superior frontal eye fields, intraparietal sulcus) and several subcortical areas, a finding broadly consistent with maturational hypotheses. However, both children and adolescents also had differential activation in regions not found to show differences in adults. Children displayed increased relative activation in the supramarginal gyrus compared to the other age groups, and the adolescents showed greater differential activity in the dorsolateral prefrontal cortex than did children or adults. These findings illustrate that the neural basis of behavior can change over developmental time, with different patterns of activation being evident at different ages, a pattern consistent with the IS and the skill-learning viewpoints.

A similar conclusion can be reached after examination of the developmental fMRI data produced by B. J. Casey and colleagues (1997; Thomas et al., 1999). These authors administered a go/no-go task to assess inhibitory control and frontal lobe function to healthy volunteers from 7 years of age to adult. The task involved participants responding to a number of letters, but withholding their response to a rarely occurring "X." More than twice the volume of prefrontal cortex activity (in the middle and superior frontal gyri) was observed in children compared to adults (for similar results, see Booth et al., 2003; Bunge, Dudukovic, Thomason, Vaidya, & Gabrieli, 2002; Durston et al., 2002; Tamm, Menon, & Reiss, 2002). One explanation of this finding is that children found the task more difficult and demanding than adults. However, children with error rates similar to those in adults showed some of the largest volumes of prefrontal activity, suggesting that task difficulty was not the important factor (Casey et al., 1997; Thomas et al., 1999). It is difficult to account for these decreases in the extent of cortical activation in terms of the progressive maturation of these areas. Some authors suggest that it reflects delayed maturation of the frontostriatal network, with the immature

network requiring greater mobilization of neural processing resources to achieve the same level of performance as the mature network (Booth et al., 2003). The finding that, for children, better performance is associated with greater activation in striatal and inferior prefrontal regions is seen as consistent with this view (Durstun et al., 2002). The finding that children and adults appeared to show different patterns of activation even when performance was equated is inconsistent with the skill-learning viewpoint, but not unexpected according to the IS viewpoint.

A third example of the use of fMRI to study the development of cortical activation patterns during childhood involved using the same stimulus array for two different tasks, a face-matching task and a location-matching task (Passarotti et al., 2003). For the face-matching task, younger children (10 to 12 years) showed more extensive areas of activation than did older children and adults. In general, the activation shown by the youngest group included the areas activated in adults (such as bilateral activation of the middle fusiform gyrus) but additionally extended to more lateral and anterior regions. In the location-matching condition, the children also showed more extensive activation than did adults. Whereas adults had strong right superior parietal activation, children displayed more bilateral activation of this structure, as well as additional activation in the right superior frontal gyrus. Once again, and in contrast to the maturational view, typical development appears to be associated with a reduction in the extent of activation of cortical areas and with dynamic changes in the interregional patterns of activation.

A fourth example of the use of fMRI to study the development of cortical activation patterns during childhood comes from studies of verbal fluency tasks in which participants are asked to generate words in response to a cue (e.g., to generate examples of a target category, or generate a verb that relates to a cued noun). Several studies have shown that adults (Lehericy et al., 2000) and school-age children (Gaillard et al., 2000; Hertz-Pannier et al., 1997) typically activate left hemisphere frontal cortical networks, including Broca's area, premotor, prefrontal, and supplementary motor areas, and, less consistently, temporal cortical areas, including superior temporal, middle temporal, and supramarginal gyri. In addition, some degree of activation in homologous right frontal regions is almost always found both in adults (Pujol, Deus, Losilla, & Capdevila, 1999; Springer et al., 1999) and in children (Gaillard et al., 2000; Hertz-Pannier et al., 1997). Two studies have found that both the degree to which activation is bilateral (rather than left-dominant) and the extent of this activation is greater in children than in adults (Gaillard et al., 2000; Holland et al., 2001). Thus, as in the other examples, typi-

cal development is associated with a reduction in the extent of activation of cortical areas and, as a consequence, an increased lateralization of activation to the left hemisphere with age (Holland et al., 2001).

Not all developmental imaging studies have reported decreases in extent of activation with age. For example, in the case of verbal fluency, two studies have reported that laterality and extent of activation did not differ between children and adults (Gaillard et al., 2000; Schlaggar et al., 2002), with one even showing a greater number of pixels activated in left frontal regions in adults compared to children (Gaillard et al., 2000). Another example comes from studies of the development of visuospatial working memory. These show that parts of the frontoparietal network involved in this task (superior frontal and intraparietal cortex) are more active in older children than in younger children, and that working memory capacity is significantly correlated with brain activity in the same regions (Klingberg, Forssberg, & Westerberg, 2002; Kwon, Reiss, & Menon, 2002). Diffusion tensor imaging studies suggest that these developmental increases in gray matter activation could be due to maturation of white matter connections within the frontoparietal network (Olesen, Nagy, Westerberg, & Klingberg, 2003). Interestingly, studies with adults also show increased activity in these areas with improvements in working memory following training (Olesen, Westerberg, & Klingberg, 2004).

In evaluating fMRI evidence for decreasing or increasing extent of cortical activation underlying a particular skill with age, it is important to be aware that factors other than dynamic changes in the interregional patterns of activation per se could be contributing to the observed differences. Of particular importance, technical aspects of data collection, including coil characteristics, head motion, and physiological age-related differences that could affect the fMRI BOLD signal, could contribute to apparent age-related differences in activation (see Gaillard et al., 2003). For example, a surface coil might identify more activated regions in children than adults because children have thinner skulls and scalp, and thus the coil is closer to the brain and can read the signal more clearly than in adults. By contrast, use of a head coil might lead to a finding of greater activation in adults than children, as most head coils are designed for adults, and thus children's head position in the coil would not be optimal. Thus, when interpreting the results of fMRI studies, it is important to keep in mind that technological and developmental factors may affect signal and noise detection that, in turn, may influence an interpretation of age-based differences in activation patterns (for further discussion of these issues, see Gaillard et al., 2003; Poldrack, 2002).

Studies that have examined developmental changes in prefrontal cortical activation are of particular interest in evalu-

ating the various viewpoints, as the skill-learning and maturational views make opposing predictions about the functioning of prefrontal regions during infancy. Work on complex motor skill-learning tasks in adults shows that the prefrontal cortex is often activated during the early stages of acquisition, but this activation recedes to more posterior regions as expertise is acquired. Thus, the skill-learning view predicts greater prefrontal activation in infants than adults when performing a simple (for adults) skill. By contrast, the maturational viewpoint would predict the opposite, with lesser involvement of prefrontal areas in younger children, due to the protracted neuroanatomical development of these regions. One of the most striking features of human infants is their initial inability to perform simple motor tasks, such as reaching for an object. In addition to the examples of prefrontal involvement described earlier, activity in this region, or at least within the frontal lobe, has been reported in a number of infancy studies where action is elicited, and early damage to these structures has more severe long-term effects than damage to other cortical regions. For example, Csibra, Tucker, and Johnson (1998) examined the cortical activity associated with the planning of eye movements in 6-month-old infants. They observed eye movement related potentials over frontal sites, but not over the more posterior (parietal) sites, where they are normally observed in adults. Converging results are obtained when eye movement tasks are studied in infants with perinatal focal damage to the cortex. Infants with damage to the frontal quadrants of the brain show long-lasting deficits in visual orienting tasks, but infants with the more posterior damage that causes deficits in adults do not (Craft & Schatz, 1994; Craft, White, Park, & Figiel, 1994; Johnson, Tucker, Stiles, & Trauner, 1998). These results overall provide little support for the maturational viewpoint and are more consistent with the other two viewpoints.

In sum, the balance of evidence to date suggests that (1) new behavioral skills or developmental changes in existing skills are often accompanied by widespread changes across many regions of the cortex, (2) functional brain development involves the twin process of increasing localization and increasing specialization, and (3) frontal cortical regions, traditionally believed to be slow to mature, may be active from early in life.

BRAIN IMAGING OF ATYPICAL DEVELOPMENT

Much of the neuroimaging work on developmental disorders to date has aimed at identifying gross abnormalities in discrete brain regions, structures, or systems. Although there have been some specific claims made with regard to

such deficits, recent reviews of the field tend to find instead that evidence is consistent with diffuse damage to widespread parts of the brain in developmental disorders. For example, Rumsey and Ernst (2000, p. 171) summarize their review of functional imaging of autistic disorders in this way: "Studies of brain metabolism and blood flow thus far have yet to yield consistent findings, but suggest considerable variability in regional patterns of cerebral synaptic activity." Other authors reviewing work on Autism concur with this conclusion. Deb and Thompson (1998, p. 299) state, "Various abnormalities of brain structure and function have been proposed, but no focal defect has been reliably demonstrated," and Chugani (2000, p. 183) concludes that "data from the various imaging modalities have not yet converged to provide a unifying hypothesis of brain mechanisms" with a range of cortical (frontal, medial prefrontal, temporal, anterior cingulate) and subcortical (basal ganglia, thalamus, cerebellum) structures implicated in different studies. According to Filipek (1999), a similar situation obtains with respect to Attention-Deficit/Hyperactivity Disorder (ADHD). She concludes that neuroimaging studies "have, in fact, confirmed the lack of consistent gross neuroanatomical lesions or other abnormalities in Attention Deficit" (p. 117). For ADHD, there are abnormalities in widespread cortical areas, including, at a minimum, the frontostriatal, cingulate, and parietal regions. In sum, for at least these two disorders, there is little support for the notion that discrete lesions to functional cortical areas can be observed in developmental disorders.

There may be some examples of developmental disorders that show a more focal pattern of brain abnormality. For example, the KE family shows a genetic disorder of speech and language involving a point mutation of the FOXP2 gene. Behaviorally, the affected members appear to have a deficit in sequencing articulation patterns that results in speech output that is often agrammatical and unintelligible (Vargha-Khadem et al., 1998; Watkins, Dronkers, & Vargha-Khadem, 2002). This impairment is evident from childhood and persists into adulthood. Recent reports indicate that the brains of affected family members differ from those of unaffected members and controls in several particular regions involved in speech and motor control. Among these, the evidence is most striking for the caudate nucleus, which shows reduced gray matter density and volume (Watkins et al., 2002) and shows abnormalities in activation during language tasks (Vargha-Khadem et al., 1998). This result might suggest that, at least in some genetic disorders, there may be discrete brain lesions that result in specific behavioral impairments, but it is important to note that the caudate nucleus is not the only brain area affected in this family and that imaging studies have not

been conducted developmentally to determine whether the pattern of damage is already present and unchanging from early in life (as the maturational or skill-learning views might predict) or evolves with development (as the IS view would predict).

Given the assumption of the maturational approach that there is a static structure-function mapping in the brain during development, it is perhaps not surprising that the vast majority of neuroimaging studies with developmentally disordered groups involve participants from middle childhood to adulthood, and that patients are often grouped together over a wide age range (e.g., Kesler et al., 2004: Turner syndrome, 7 to 33 years; Pinter, Eliez, Schmitt, Capone, & Reiss, 2001: Down syndrome, 5 to 23 years). For the interactive specialization approach, however, age of testing is critical, and it is especially important to study infancy to understand partial causes of subsequent outcomes (Karmiloff-Smith, 1998; Paterson, Brown, Gsödl, Johnson, & Karmiloff-Smith, 1999). For this issue to be assessed, there need to be longitudinal imaging studies of clinical groups, or at least cross-sectional study at different ages. Due to the difficulties mentioned earlier, there are very few examples of studies of brain function in infants with developmental disorders. Where these have been investigated, there is evidence that abnormalities in brain structure and function may appear differently at different ages. For example, Karrer, Wojtaszek, and Davis (1995, p. 146; see also Hill-Karrer, Karrer, Bloom, Chaney, & Davis, 1998) conducted an ERP study of infants with Down syndrome at 6 months using an oddball paradigm for face recognition and concluded that “infants with Down syndrome may have more subtle differences (to age matched controls) than those found in adults with Down syndrome.” There are few MRI studies of developmental disorders that have compared different age groups in infancy or childhood. One recent study of Autism found evidence of hippocampal enlargement at all ages but amygdala enlargement only in children (7.5 to 12.5 years) but not adolescents (12.75 to 18 years; Schumann et al., 2004). Though few in number, these examples are consistent with the IS view that brain abnormalities in developmental disorders are not like static lesions but can change as the brain develops.

One basic question that can be addressed is whether an abnormal end state is the result of an aberrant trajectory of development or a normal developmental trajectory is merely delayed. Ideally, the question should be investigated by longitudinal studies of the developmental disorder group in question. However, in the absence of such data, the question can be asked whether the phenotypic end state of the disorder resembles any stage of the typical developmental trajectory.

If so, this could be evidence for delayed development. This approach has been taken to investigating the neurochemistry of Autism. Specifically, do individuals with Autism show a profile consistent with a delayed, but otherwise typical, developmental trajectory? Positron emission tomography (PET) studies have identified brain glucose metabolism in Autism that is higher than in age-matched controls (see Chugani, 2000, for review). However, in typical development, there is a characteristic rise and fall of glucose metabolism that parallels changes in synaptic density in the cortex. Muzik and colleagues (1999) generated a mathematical developmental function with identifiable parameters representing different stages of typical development. This allows closer comparison with developmentally disordered groups when longitudinal data are obtained. Thus, evidence for higher brain glucose metabolism (and therefore, indirectly, excess synaptic density) in Autism suggests a delayed, rather than aberrant, profile. However, a caveat to this endorsement is that in the developmental cortical network models studied by Oliver, Johnson, Karmiloff-Smith, and Pennington (2000), reduced synaptic pruning was a symptom of several *different* simulated neural networks that failed to form adequate representations of input stimuli. It is possible, therefore, that reduced synaptic pruning (and therefore elevated glucose metabolism) will be a symptom shared by several different groups with developmental disorders.

According to the maturational view, behavioral abnormalities are caused by psychological deficits that in turn are caused by functional “lesions” to the brain. In functional neuroimaging paradigms, therefore, the general expectation is that there will be fewer regions active in the disordered group than in controls, and that the regions active in controls but not in the disordered group are the neural locus of the deficit. This fits well with the subtraction methodology often employed in functional neuroimaging studies. For example, one fMRI study comparing 8-year-old children who had been born preterm or full-term found that preterm children did not activate the normal network during a semantic processing task but instead activated a network that closely resembled that used by full-term children during a phonologic processing task (Peterson et al., 2002). Furthermore, the greater the apparent reliance on the phonological pathway by preterm children, the poorer their verbal comprehension. In the maturational view, this result would be interpreted as suggesting that the brain areas involved in semantic processing were damaged in the preterm children and caused their impairments in verbal comprehension. In contrast to this view, the IS approach views developmental disorders in terms of brains that develop differently from the typical trajectory from the start. This view predicts that

differences in functional activation will be seen between groups, but that this could even involve more widespread activation in developmental disorders. In other words, different patterns of regional activation may be seen for developmentally disordered groups in a given task, rather than one or more regions being functionally silent.

A further prediction of the IS view is that even if areas of behavioral competence are examined, there will still be differences in the neural processing underlying this performance (Karmiloff-Smith, 1998). This question has been examined in studies of Williams's syndrome, a syndrome portrayed by some theorists as involving islands of "sparing" (normal performance) amid clear deficits. Mills and colleagues (2000) focused on an area of behavioral competence in this disorder, face processing, and recorded ERPs during a face-matching task. Despite their "intact" behavioral performance in the task, participants with Williams's syndrome displayed different patterns of ERPs, including a lack of the normal right hemisphere asymmetry. Similar findings were obtained in another area of behavioral competence for this syndrome, where the normal left hemisphere asymmetry for words was not observed (Mills et al., 1993; Neville, Mills, & Bellugi, 1994). ERPs in response to faces have also been recorded in participants with Autism and Asperger's syndrome (McPartland & Panagiotides, 2001). However, in this case, face processing is an area of behavioral deficit. Compared with controls, the Autism group made more errors on a test of face recognition. Performance on the face recognition task was found to be related to the ERPs in several ways. In controls, a face-sensitive ERP component was larger in amplitude to faces compared with objects and was more predominant over the right hemisphere. In contrast, the autistic group showed longer latencies of this component to faces compared to objects, in the absence of any clear lateralization. These findings suggest that the poorer performance on face recognition tasks by the Autism group is reflected by slower and less lateralized (i.e., less specialized) processing of faces, as indicated by their ERPs. In addition, the different distribution of the response to faces between the autistic group and controls may reflect qualitatively different processing strategies.

EFFECTS OF EARLY ACQUIRED BRAIN DAMAGE

Both the maturational and skill-learning views would predict that early brain damage should have long-lasting detri-

mental effects, because the neural substrates through which an ability emerges or is learned and retained are destroyed. The maturational view allows for plasticity in response to such damage, but it makes no clear prediction that the extent of such plasticity should be greater for children compared to adults. The skill-learning view might predict, at least under some circumstances, more negative outcomes for early lesions to areas involved in skill acquisition, because adults would have already-learned, retained skills to fall back on, whereas children would have fewer established skills. In the IS view, however, there may be compensation for early damage. Although the damage may affect the areas that under normal circumstances would be most suitable for the task and become specialized for it, if the area is damaged early in life there is still scope for alternative neural circuitry to be recruited for the task. It is possible that this compensation could come at some price, however, as the overall amount of brain area that can take on specialized functions would be reduced (e.g., the notion of crowding; for discussion, see Vargha-Khadem & Mishkin, 1997). If the area is damaged later in life, the outcome may be less optimal, as brain areas would already have specialized for particular skills and there would be less scope for alternative neural circuitry to be recruited, as it will already be taken up by other tasks. In this section, we evaluate evidence relating to these hypotheses from studies of the effects of early lesions in three cognitive domains: face processing, memory, and language.

Face Processing

In adults, damage to the occipitotemporal cortex can result in prosopagnosia, a selective impairment in face processing. Recently, several cases of selective deficits in face processing attributed to damage sustained in infancy have been reported (developmental or congenital prosopagnosia; e.g., Bentin, Deouell, & Soroker, 1999; Farah, Rabinowitz, Quinn, & Liu, 2000; Jones & Tranel, 2001; Nunn, Postma, & Pearson, 2001). On the surface, these results are consistent with both the maturational view (early damage to the cortical face-processing system would result in a functional impairment similar to that in adults with similar damage), and the skill-learning view (early damage to the system involved in learning about faces will result in a persistent impairment in this ability). However, there are some characteristics of developmental cases of prosopagnosia that do not seem to fit either of these views. If the maturational view is correct, then it would be expected that the location of damage causing prosopagnosia would be the same in both early- and adult-onset cases (Damasio, Tranel, & Damasio,

1990). However, of the few early-onset cases where structural imaging was obtained, there was no observable structural damage (Nunn et al., 2001) or diffuse rather than focal abnormalities (Laeng & Caviness, 2001). Thus, the impairments in face processing observed do not appear to be a direct consequence of focal damage to brain areas involved in face processing in adults.

If the maturational view or the learning view were correct, then one would also expect the nature of the face-processing deficit to be similar in early- and adult-onset cases. Although some authors have concluded that the two disorders are basically similar in terms of an impairment in encoding for spatial arrangement of facial evidence (Barton, Cherkasova, Press, Intriligator, & O'Connor, 2003), there is some evidence for differences related to age of onset: Residual discrimination abilities are more limited in developmental cases (Barton, Cherkasova, & O'Connor, 2001), and covert recognition is absent in developmental cases (Barton et al., 2001; Jones & Tranel, 2001). These results are more consistent with the IS view, which would predict that the nature of the deficit would depend on the age of injury.

Other studies have taken a different approach. Instead of finding individuals with face-processing deficits that could be attributed to early lesions, these studies have found children who sustained lesions to areas known to be involved in face processing in adults and investigated the consequences for face processing. In one study of face-processing abilities in 5- to 14-year-olds who had experienced perinatal unilateral lesions, the effects were fairly mild: Fewer than half of the children showed impaired performance relative to controls on tests of face or object identity recognition (Mancini et al., 1998). Furthermore, (1) face-processing deficits were no more common than object-processing deficits following a right hemisphere lesion, (2) face-processing deficits were no more common after right-sided than left-sided damage, and (3) a face-processing deficit never occurred in the absence of an object-processing deficit. This general pattern is similar to that reported in other studies (Ballantyne & Trauner, 1999; Mancini, de Schonen, Deruelle, & Massoulier, 1994) and contrasts with the severe impairments in face and/or object recognition observed in adults with damage to similar brain regions (Farah, 2000).

Together, these results suggest that the infant face-processing system is more widely distributed and/or more plastic following damage than is the adult system. These results fail to provide convincing evidence for the maturational view or the skill-learning view. Instead, they are more consistent with the IS view that, when brain areas

that typically mediate a function in adults are damaged early in life, there may be greater recovery of function than that following similar damage in adults.

Memory

Memory is among the most fundamental aspects of cognitive development, enabling individuals to amass knowledge about the world (semantic memory) and to recall everyday events (episodic memory). In adults, bilateral damage to the medial temporal lobe results in a global amnesia, reflecting this region's essential role in explicit memory. However, until recently, there were virtually no reports of memory impairments following temporal lobe damage in children. This was assumed to be either because the results of such damage were so devastating to the developing child that a global severe mental delay resulted (consistent with the skill-learning view) or because the greater plasticity of the developing brain allowed sufficient recovery to prevent clinical appearance of memory impairments (consistent with the IS view). In recent years, however, there have been reports that very early damage to a specific medial temporal lobe structure, the hippocampus, does result in amnesia (Gadian et al., 2000; Isaacs et al., 2003; Vargha-Khadem et al., 1997, 2003). On the surface, this finding appears consistent with the maturational view, in that early focal damage to a brain region believed to mediate a particular ability in adults results in a specific failure of that skill to develop. Indeed, the pattern of memory impairment observed in these children, where episodic memory is relatively impaired and semantic memory relatively spared, has been used to argue that the hippocampus is necessary for episodic memory in adults (Vargha-Khadem et al., 1997). However, the results of selective, bilateral hippocampal damage occurring in childhood appear to differ from those of similar damage occurring in adulthood (Baddeley, Vargha-Khadem, & Mishkin, 2001; Gadian et al., 2000; Vargha-Khadem et al., 1997). The deficits following early injury appear more subtle: Whereas hippocampal damage in adulthood typically results in deficits in both semantic (facts) and episodic (events) memory, damage during childhood results in clear deficits only in episodic memory, showing relatively normal development of semantic memory. For example, these children score in the low-average to average range on indices of semantic memory, such as general intellectual abilities and academic attainments, but they are severely impaired on indices of episodic memory, such as remembering a name, a message, or where a belonging was placed (Gadian et al., 2000; Vargha-Khadem et al., 1997, 2003). Also, in cases with

neonatal damage, the memory deficits that these children display become apparent only about the time they first enter school or even later.

Proponents of the maturational or skill-learning view might argue that this difference in outcome can be explained by a difference in the selectivity of the medial temporal lobe between the two conditions, such that whereas the hippocampus is damaged in both, only the patients with early-onset damage show substantial sparing of the subhippocampal cortices. This possibility is in line with the suggestion that the hippocampus and the subhippocampal tissue serve different components of explicit memory, with the hippocampus mediating episodic recollection and the subhippocampal cortices mediating semantic memory and familiarity-based recognition (Baddeley et al., 2001; Mishkin, Vargha-Khadem, & Gadian, 1998). However, in the IS view, this difference in outcome can be explained by the fact that the degree of postinjury compensation and reorganization differs between the developing and the mature brain, such that only early damage allows for recovery of the functions found to be spared in early-onset amnesia. As there has currently been no published report directly comparing early-onset with adult-onset amnesia controlling for extent of damage, it is difficult to decide between these two possibilities. One piece of evidence in favor of the maturational view is a recent report indicating that, in the early-onset cases, there is no difference in the degree of long-term memory impairment for those sustaining damage before 1 year of age and those sustaining the damage between 6 and 14 years (Vargha-Khadem et al., 2003). There was evidence of a difference between the groups only on a few tests of immediate recall, where those with neonatal damage performed better than those with later damage.

Interestingly, a functional imaging study of one patient with developmental amnesia (injury neonatally, tested at 22 years of age; Maguire, Vargha-Khadem, & Mishkin, 2001) showed that, although his hippocampi are severely damaged (approximately 50% reduced in volume bilaterally), they are activated in tasks in which controls also activate the hippocampus. Specifically, during retrieval of real-world memories, the patient, Jon, activated the same brain regions as controls, including the hippocampus. Also like controls, activation in Jon's hippocampus was greater for the few autobiographical events he could recall compared to public events and general knowledge. However, in spite of these qualitative similarities, his hippocampal activation was actually greater than controls'. Specifically, he activated many homologous areas on the right that the controls did not, and he also showed a different pattern of connectivity between areas compared to controls (controls showed in-

creased connectivity of hippocampal with parahippocampal regions during retrieval of autobiographical events, whereas Jon showed increased connectivity between the hippocampus and retrosplenial cortex and the medial frontal cortex and retrosplenial cortex). These results are difficult to explain in the maturational view, but could be accounted for by the skill-learning view (Jon activates a different network because he has less memory ability) or the IS view (Jon activates a different network because his early lesions have led to reorganization and compensation).

Language

In adults, left hemisphere lesions that involve perisylvian areas result in a dramatic impairment of speech and language that is typically chronic despite rehabilitation. By contrast, damage to these regions during childhood appears to have no or only subtle effects on ultimate language abilities, and there appear to be no or only subtle effects of side of injury (in cases uncomplicated by epilepsy; e.g., see Bates & Roe, 2001; also reviewed in Vargha-Khadem, Isaacs, Watkins, & Mishkin, 2000). For example, one direct comparison of children (5 to 8 years) and adults found the classic association of left-sided damage with aphasia in adults, but found that children performed within the normal range, with no effect of lesion side (Bates et al., 2001). This result is inconsistent with the maturational view, which would predict a similar pattern of impairment in cases of childhood injury. It is also difficult to reconcile with the skill-learning view, unless the damaged areas are not involved in language learning and are only critical once the skill is fully acquired.

There is some evidence consistent with the idea that the left perisylvian areas critical for language in adults may not be key in language learning in children. This comes from data showing that even in early damage there are significant effects of lesion side and site on first stages of language development, but not involving the left perisylvian areas. For example, early delays in word comprehension and symbolic gesture are somewhat more common with perinatal right hemisphere damage, but only between 10 and 20 months of age (Vicari et al., 2000), and deficits in expressive vocabulary and expressive grammar are more common with perinatal left temporal lobe damage, but only from 10 months to 5 to 6 years (Thal et al., 1991). One interpretation is that, when children are struggling to reproduce familiar sounds from their input language for the first time, they have to extract a great deal of perceptual detail from the input. This might normally rely on the left temporal cortex, because it is known to be involved in extracting

detail from perceptual inputs. This explanation is consistent with the skill-learning view and the IS view.

Overall, evidence suggests that younger children may have less consolidated and more bilateral representations of language-processing areas, which derives mostly from increased activation in the right frontal lobe (Gaillard et al., 2000; Holland et al., 2001). For example, PET studies of children who had neurosurgery to treat intractable epilepsy indicate that, especially for language perception tasks, early left hemisphere lesions are associated with enhanced activation of right hemisphere areas, whereas recruitment of regions ipsilateral to the lesions side is limited. Thus, a more diffuse, less consolidated distribution of language networks has been proposed as an explanation for recovery from dominant hemisphere brain injury in children that extends, with diminishing capacity, into adolescence (Boatman et al., 1999; Gaillard et al., 2000; Vargha-Khadem, Isaacs, van der Werf, Robb, & Wilson, 1992). It has been argued that, by adulthood, the functional role of the right hemisphere in aphasia recovery may be more limited compared with that of the perilesional structures in the left hemisphere (Karbe et al., 1998; Weiller et al., 1995).

EFFECTS OF ATYPICAL EARLY EXPERIENCE

The three perspectives on human functional brain development differ in their views as to the effects of early atypical experience. In the maturational view, differences in experience might influence the speed at which a function matures or the ultimate level of performance; in the skill-learning view, any atypical early experiences can potentially be compensated for later in development as the mechanisms for learning remain in operation in the same way; in the IS view, atypical early experiences may have long-lasting effects because they could affect the specialization and localization of function, which may not be able to be altered later in life, when there is less scope for plasticity.

There have been only a limited number of studies examining the effects of atypical early experience in humans. Several studies have examined the influence of early experience on processing of facial information. For example, Pollak and colleagues have found that perception of the facial expression of anger, but not other expressions, is altered in children who experienced the culturally atypical environment of parental abuse. Specifically, they report that, compared to nonabused children, abused children show a response bias for anger (Pollak, Cicchetti, Hornung, & Reed, 2000), identify anger based on less perceptual input (Pollak & Sinha, 2002), show altered category bound-

aries for anger (Pollak & Kistler, 2002), and show atypical responding to anger on tasks of selective attention (Pollak & Tolley-Schell, 2003). These results suggest that atypical frequency and content of their emotional interactions with their caregivers results in a change in the basic perception of emotional expressions in abused children. Specifically, in this case, children seem to show a hypersensitivity to anger, a finding also supported by ERP studies with this population (Pollak, Cicchetti, Klorman, & Brumaghim, 1997; Pollak, Klorman, Thatcher, & Cicchetti, 2001). However, whether these effects would disappear with sufficient exposure to a normative environment, as the skill-learning view might predict, or reflect more lasting effects, as the IS view might predict, is not clear.

Other studies have taken a different approach and investigate the perception of facial information in children who experienced deprivation of patterned visual input in the early months of life due to bilateral, congenital cataracts. These patients were tested years after their cataracts were removed and they were fitted with contact lenses (i.e., years after visual input had been restored), thus any effects of the few months of deprivation following birth would likely be absent or very minimal, according to the maturation and skill-learning views. However, investigation of these patients reveals persistent deficits in selective aspects of face processing. One study found that patients showed impairments in matching facial identity over changes in viewpoint (and tended to show an impairment in recognizing identity over changes in emotional expression), but performed normally on tests of lip reading, perception of eye gaze, and matching of emotional expressions (Geldart, Mondloch, Maurer, de Schonen, & Brent, 2002). A second study demonstrated that this difficulty in processing facial identity may be due to deficits in processing the spacing among facial features, because patients performed normally in discrimination of faces that differed only on individual features (e.g., mouth), but they were impaired in discrimination of faces that differ only in the spacing of the features (Le Grand, Mondloch, Maurer, & Brent, 2001, 2003, 2004). This was not due to a general impairment in perception of spacing of features, as they performed normally in discriminating nonface patterns whether they differed by the shape of the features or the spacing of the features. These patients also show impairments in holistic processing of faces, which actually allows them to perform better than controls on certain tasks where optimal performance relies on ignoring the whole and focusing on the features (Le Grand et al., 2004). The fact that these impairments persist even after years of visual input to compensate for the early deprivation is not consistent with the

maturational or skill-learning views, but is consistent with the IS view that early atypical experience may have long-lasting consequences.

Early experience has also been studied in the context of language development. One question of interest here has been whether adults' second-language acquisition activates the same network as the primary language learned during childhood (consistent with the skill-learning and maturational views) or a different network (consistent with the IS view). Some early reports indicated that bilinguals who learned their second language late showed different activations for the two languages, whereas bilinguals who learned their second language early showed overlapping activations (e.g., Kim, Relkin, Lee, & Hirsch, 1997). However, subsequent studies have suggested that level of skill in the second language, rather than age of acquisition, is the more important variable in determining the degree of overlap of regions activated by the two languages (e.g., Chee, Tan, & Thiel, 1999; Dehaene et al., 1997; Perani et al., 1998), a result consistent with a skill-learning view.

A slightly different approach has been taken by other studies, questioning whether early exposure to a language has any long-lasting consequences. These studies have examined adults who early in life were exposed to one language for a few months or years but then were removed from that language and exposed to another one either because of adoption or emigration. One study examining Korean adults adopted between 3 and 8 years of age by French families found no evidence that the subjects could identify Korean words and no differences in brain activation to Korean versus unknown languages, but did find that the brain activation for French, though it involved the same basic network, was more widespread in the native speakers than in the adoptees (Pallier et al., 2003). Another study found that children who had heard or heard and spoken Korean during the first years of life later showed benefits from this limited early experience in learning Korean during the 1st year of college (Oh, Jun, Knightly, & Au, 2003). These lasting effects of limited periods of early exposure are difficult to explain in the maturational or skill-learning view points, but can be explained in the IS view as the effects of early experience on the specialization of the areas involved in processing speech and language.

CONCLUSIONS

The three perspectives on human functional brain development have different implications for our understanding of developmental disorders and the effects of brain damage

over the first years of life. In the maturational view, genetic disorders could potentially lead to focal cortical damage and consequently to selective cognitive, motor, or perceptual disorders. Symptoms of these disorders would first become evident at the normal age of maturation of the regions concerned. However, recent reviews have concluded that there are few, if any, human developmental abnormalities of genetic origin that affect only one or two specific regions of the cortex (Johnson et al., 2002). Rather, structural and functional neuroimaging usually reveal subtle but widespread differences in the brains of groups with developmental disorders. Relatedly, claims of domain-specific cognitive deficits in syndromes such as Autism and Williams's syndrome have been challenged, replaced with hypotheses about different styles or modes of processing (e.g., Karmiloff-Smith, 1998). Finally, it is difficult to explain reports of recovery of functions following early brain damage by the maturational view, without recourse to additional special mechanisms of plasticity.

According to the interactive specialization view, developmental disorders of genetic etiology will often involve disruption of the typical biases and interactions between regions that give rise to adult patterns of cortical functional specialization. In this view, subtle symptoms should be evident from birth, but these will become compounded through the infant's abnormal interactions with its environment. Although there are currently few behavioral studies of developmental disorders during infancy, those that do exist suggest discontinuities in the patterns of behavioral and cognitive deficits through postnatal development. For example, in one such disorder, Williams's syndrome, adults present with behavioral deficits in number tasks but show surprising proficiency in some aspects of language. One study investigated whether this pattern of specific deficits is also observed in infants with Williams's syndrome, as would be expected if they have a damaged innate module for number. Standard infant paradigms for assessing number and object-naming skills were used with toddlers with Williams's syndrome (Patterson et al., 1999). The toddlers did not show the same behavioral profile as observed in adults with the syndrome, indicating that the profile of behavioral deficits in developmental disorders can change during ontogeny and that it is not appropriate to characterize such deficits in terms of damage to domain-specific modules. From the interactive specialization perspective, it may also be easier to understand recovery of function following early damage, as the same mechanisms that ensure specialization during the typical developmental trajectory could ensure a different pattern of specialization.

Both the skill-learning and IS viewpoints share the assumption of dynamic mapping, and this common assumption is overall supported by the evidence reviewed in this chapter. The main points on which these two views differ is regarding whether the brain areas involved in a task are similar or different in children versus adults who have attained a similar level of performance, and whether plasticity decreases with age. There have been relatively few studies directly assessing the former point, and studies aimed at the latter point have been more clearly consistent with the IS view in some domains (e.g., impact of brain injury on language) than others (memory, face processing).

FUTURE DIRECTIONS

Further assessment of the three perspectives on human functional brain development presented in this chapter will require more improved methods for noninvasive functional imaging and more detailed computational models that generate predictions about both neuroanatomy and behavior. With regard to new functional imaging methods, forms of optical imaging (near-infrared spectroscopy, NIRS) offer promise for studying brain function in human infants (Meek, 2002). Like fMRI, NIRS can measure changes in blood oxygenation in the brain that occur following the activation of groups of neurons within an area. Although currently lacking the spatial resolution of fMRI, the method does not involve the exposure to high magnetic fields, noise, and motion sensitivity that make using fMRI with typical infants difficult.

From the age of 6 or 7 years, MRI can be routinely used. Recent advances in MRI analysis techniques will allow the investigation of both structural and functional changes during development. The recent studies using diffusion tensor imaging (DTI) to track the development of white matter demonstrate its usefulness for understanding not only structural brain development but also the functional development of brain networks underlying emerging cognitive skills. For example, a recent study used DTI together with fMRI to study the development of the frontoparietal network involved in working memory. These authors found that DTI measures of frontoparietal white matter correlated with the fMRI response in closely located gray matter in the superior frontal sulcus and inferior parietal lobe. These results suggest that development of white matter could account for increases with age in level of activation of frontoparietal gray matter observed during working memory tasks (Olesen et al., 2004).

The basic method of EEG/ERP has been available for over 50 years, and recent advances in technology and analysis methods have opened up new possibilities for the exploration of brain function in infants and young children. In one such advance, high-density recording systems along with new algorithms for the statistical separation of sources allow better localization of the underlying brain generators of scalp-recorded voltage changes (e.g., Johnson et al., 2001). In another advance, the relation of bursts of high-frequency oscillatory activity in the brain to cognitive and perceptual tasks has begun to be studied in infants, children, and adults (e.g., Csibra, Davis, Spratling, & Johnson, 2000). In one experiment, high-frequency oscillations occurred during periods of time when previously visible objects became occluded, potentially providing a neural correlate of object permanence (Kaufman, Csibra, & Johnson, 2003).

To relate findings on brain structure and development to those on perceptual or cognitive functions, we need the explanatory bridge that can be provided by computational modeling of neural networks. There are major efforts to use connectionist models to explain aspects of typical and atypical cognitive development (Thomas & Karmiloff-Smith, 2002), but very few of these efforts currently allow interpretation of data from functional imaging or neuroanatomy. These types of investigations will provide information regarding which of the three viewpoints best describes the developmental process, and whether the answer to this question depends on the cognitive domain under study and the context in which it develops. Whatever the outcome of these investigations, a better understanding of functional brain development in human infants and children may have profound consequences for educational, clinical, and social policies.

For many decades, the prevailing view concerning disorders of the central nervous system was that they were either neurological or psychiatric in nature. Neurological disorders were considered to be those that altered the substance of the brain; psychiatric disorders were those that involved the emotions and were functional in nature. With the advent of pharmacological agents effective in the treatment of psychosis, depression, and anxiety, it became clear that a mental illness might entail alterations of brain circuitry and, in this respect, bear some similarity to the neurological disorders. This perspective has provided an impetus for

investigations of the pathophysiology and treatment of mental illness that have burgeoned over the past 30 years. This period has been characterized by a significant change in the approach of psychologists and neuroscientists to the study of psychopathology (Cicchetti, 1993; Cicchetti & Cannon, 1999; Cicchetti & Sroufe, 2000; Rutter & Sroufe, 2000) and how we conceptualize the etiology of mental illness during childhood, adolescence, and adulthood (Benes, 1995). Specifically, multiple levels of analysis are needed to understand how adaptation versus maladaptation contributes to normal and abnormal development, respectively

(Cicchetti & Dawson, 2002). Although Schizophrenia has been more extensively studied in recent years, affective and anxiety disorders also are addressed.

A popular hypothesis for the etiology of Schizophrenia has been that patients with this disorder might have excessive amounts of dopaminergic activity (Carlsson, 1978). With previous family studies revealing a higher incidence of Schizophrenia among the relatives of schizophrenics (Kety, Rosenthal, Wender, & Schulsinger, 1968), it was suggested that a genetic factor might be responsible for the proposed increase of dopaminergic activity (Kety & Matthysse, 1972). Viewing Schizophrenia as a genetically transmitted disorder, however, left certain clinical observations unexplained. For example, the concordance rate for Schizophrenia among monozygotic twins was found to be only 40% to 50% (Gottesman & Shields, 1972; Kety, 1983), making it virtually impossible to explain the occurrence of this disorder solely on the basis of an inherited trait. In addition, because many schizophrenics show a characteristic deterioration of functioning during the first several years of illness, at one time it seemed that a neurodegenerative process might be involved in the etiology of this disorder. It is noteworthy that several studies have indicated that schizophrenics as a group have a much higher than expected incidence of obstetrical complications (Jacobsen & Kinney, 1980; Keshavan, 2003; Parnas et al., 1982). More recently, subjects with Bipolar Disorder have also been found to have similar birthing histories (Kinney, Yurgelun-Todd, Tohen, & Tramer, 1998; Kinney et al., 1993). The most prevalent type of birth complication noted was prolonged labor. Because this is thought to be associated with hypoxemia, some believed that an early brain insult occurring in this setting might be a risk factor for Schizophrenia.

It has long been thought that Schizophrenia might represent a heterogeneous group of disorders, with some patients having a genetically transmitted disease and others a neurodegenerative one. This idea has had some appeal because these two etiologies could potentially explain some of the differences in the clinical appearance of schizophrenic patients. For example, some patients show a preponderance of so-called positive symptoms, such as hallucinations and delusions, and others show a preponderance of negative symptoms, such as poor motivation, flat affect, anhedonia, and anergia. Schizophrenics with prominent negative symptoms were found to be more likely to show volume loss in computerized axial tomography scans of their brains. This typology, however, has failed to account for the fact that most schizophrenic patients show the occurrence of both positive and negative features and cannot be easily segre-

gated into these two distinct categories. In addition, obstetrical complications alone could not explain the occurrence of neurodegeneration because birth complications are not exclusively found in the past records of schizophrenics. For example, individuals with cerebral palsy have experienced profound brain damage from severe anoxia early in life but carry no increased risk for Schizophrenia. It seemed that a two-factor model for Schizophrenia might better explain these various observations (Parnas et al., 1982), although more recently, some have come to believe that even a five-factor model may be appropriate (Serretti & Olgiati, 2004). According to the two-factor model, if a subtle brain insult occurs in the setting of susceptibility genes for Schizophrenia, then perhaps the two together could give rise to the disorder. Accordingly, a model of Schizophrenia in which both an early brain insult and a predisposing genetic trait are necessary for its occurrence (Parnas et al., 1982) seems more plausible. Such a two-factor model of Schizophrenia is consistent with Hebb's (1949) idea that both constitution and environment play central roles in the occurrence of mental illness. Interestingly, a model of this type could help explain some of the heterogeneity of Schizophrenia as a result of varying degrees of brain insult and/or genetic loading. Moreover, the precise time during early development when a brain insult occurs could further determine the specific aspects of brain circuitry that are disrupted, and this, in turn, might influence the specific behavioral manifestations that are observed clinically.

A key issue for a two-factor model of Schizophrenia is to identify the susceptibility genes for the disorder. Although evidence for a primary defect in dopamine transmission has not been forthcoming, some investigators have looked to other, more accessible phenotypic markers. For example, alterations of smooth-pursuit eye movements that have been found in both schizophrenics and their first-degree relatives could be related to a fundamental difference in the constitution of an individual who carries a gene for Schizophrenia (Holzman et al., 1988). Similarly, the schizotypal personality trait, which is more prevalent among the first-degree relatives of schizophrenics than it is among those without Schizophrenia (Kety, 1985), could also represent a predisposing constitutional trait (Parnas et al., 1982). Because schizotypes characteristically are withdrawn, are suspicious, have magical thinking, and experience some perceptual disturbances (*Diagnostic and Statistical Manual of Mental Disorders IV*, American Psychiatric Association, 1994), it is not difficult to imagine that an individual with such a personality profile, when exposed to an early brain insult, could develop the more exaggerated symptoms seen in Schizophrenia. Thus far, other

types of clinical markers, such as antisaccades (Levy et al., 2004) and visual motion integration (Chen, Bidwell, & Holzman, 2005; Levy et al., 2004), have not been found to be cofamilial traits for Schizophrenia.

The discussion that follows addresses the question of how developmental neurobiology can provide a framework for investigating the nature, course, and etiology of psychiatric disorders. The chapter begins with a discussion of how we might conceptualize the interaction of constitution with environment in determining patterns of human personality and behavior. Next, the basic nature of personality is discussed in relation to several core defects in Schizophrenia that may help identify corticolimbic brain regions involved in aspects of the personality that are disturbed in Schizophrenia. This is followed by a review of the ontogenesis of corticolimbic brain areas and the major neurotransmitter systems found in them. This latter discussion lays the groundwork for a description of some recent post-mortem findings in Schizophrenia research and a discussion of how neurodevelopmental disturbances theoretically could have given rise to them. Finally, the chapter concludes with a discussion of the future directions that neurobiologic studies of Schizophrenia and other psychiatric disorders, such as Bipolar Disorder, might follow so that a neurodevelopmental understanding of mental illness can eventually emerge. Overall, a basic premise of this discussion is that information in the brain is processed by distributed groups of neurons that maintain a functional interconnection based on experiential demands rather than by a strictly genetically determined scheme (Cicchetti & Dawson, 2002).

CONSTITUTION AND THE ENVIRONMENT AS DETERMINANTS OF PERSONALITY AND VULNERABILITY

Through the pioneering work of Jerome Kagan, the idea that there is a neurobiologic basis for constitutional differences among human subjects has gained widespread acceptance. This concept has grown out of the observation that a distinct subgroup of children can be identified by their fearful response to novel settings (Kagan, Reznick, Snidman, Gibbons, & Johnson, 1988). These so-called inhibited children show distinct changes in heart rate, blood pressure, and glucocorticoid release when presented with unfamiliar settings (Kagan, Resnick, & Snidman, 1988). A similar constitutional subtype in cats is also recognized. These “harm-avoidant” cats show a reduced ability to in-

teract socially with strangers and tend to hide when presented with novel stimuli (Adamec, 1991). In these fearful felines, there is an increase in the firing of neurons in the basomedial amygdala and the ventromedial hypothalamus (Adamec, 1978). It is noteworthy that the harm-avoidant temperament in cats appears very early in postnatal life, when early experience tends to bring out innate differences in temperament (Adamec, Stark-Adamec, & Livingston, 1980). For example, kittens showing more exploratory tendencies show aggressive responses to rats, whereas those with harm-avoidant tendencies become defensive when exposed to rats early in development. If a defensive cat is exposed to a dead prey, a decrease of defensive behavior is noted. Thus, postnatal experience may modify the basic temperament of cats (Adamec et al., 1980). The inhibited temperament in children also shows a tendency for postnatal modification (Kagan, Reznick, & Gibbons, 1989; Kagan, Reznick et al., 1988; Kagan & Snidman, 1991a, 1991b). For example, when inhibited children were reevaluated at age 4, their harm-avoidant patterns, in many instances, were less apparent. Experiential factors, such as parental reinforcement of nonavoidant behaviors, might serve to modify basic constitutional tendencies and become integrated as part of a child’s temperament. Results from behavioral and neuroimaging studies support the view that continued development of emotional expression is related to the functional maturation of specific neural regions, such as the amygdala, throughout childhood and adolescence (Herba & Phillips, 2004).

The idea that aspects of the temperament are environmentally influenced was first suggested by the observations of Spitz (1949) of children reared either in a stimulus-enriched, nurturant environment or in an environment with both social and sensory isolation. The latter group developed an “anaclitic” depression characterized by withdrawal, lack of curiosity, and infection proneness. An animal model for environmental effects on the development of behavioral characteristics was later developed in primates to investigate whether social isolation during critical periods of early postnatal life might result in a permanent tendency toward social isolation (Harlow, 1958; Harlow, Dodsworth, & Harlow, 1965). It was found that isolative behavior can be modified by exposure of young monkeys to other, more gregarious monkeys.

Cloninger (1991) described two additional basic temperaments identifiable in humans. The “novelty-seeking” type includes features such as exploratory excitability, impulsiveness, extravagance, and disorderliness; the “reward-dependent” type shows sentimentality, persistence, attachment, and dependence. As suggested earlier, the

schizotypal personality may be another constitutional variant in humans. It would be difficult to fit every individual into such categories, but aspects of several prototypes may occur in a variety of permutations and account for the diverse array present in the general population.

This discussion supports the general notion that an innate tendency toward certain behavioral responses occurs in higher mammals, particularly humans, but this can be modified by experience early in life. Each individual may carry a predisposition to certain types of basic behavioral responses, but it is likely that each also has experienced extensive modification of a constitutional framework through environmental experience. It might be operationally useful to define the individual personality as a complex function in which a dynamic equilibrium exists between basic constitution and cumulative experience (environment; Figure 5.1). According to such a model, constitution and experience would be interacting throughout the lifetime of an individual, and both would have the ability to continually modify the other. The cumulative experience of an individual and its interplay with basic constitutional tendencies would influence not only how that person responds to subsequent experience, but also how normal changes in brain maturation (see following discussion) might alter the overall response set or personality of the individual. The idea that personality is not immutable, but fluid, has come from the provocative work of Vaillant (1983), in which the “alcoholic personality,” with its passive, dependent features, was found to be a state-dependent phenomenon. Individuals who have abstained from alcohol for long periods of time do not show this profile.

Figure 5.1 Interaction of constitution and environment as determinants of personality. Constitution may be a genetically defined set of behavioral responses that interplay with environmental events. During the life of an individual, these two factors interact in a reciprocal fashion and give rise to what we identify as “personality.” In individuals at risk for mental illness, constitution may impart selective vulnerability to individuals who have various abnormal genes related to the psychiatric disorders. In such individuals, environmental factors can influence whether and/or the degree to which the selective vulnerability is expressed.

With regard to the question of how postnatal development may play a role in the occurrence of the mental disorders, the previous remarks provide some clues. Each individual who presents with a particular mental disorder may have a preexisting set of constitutional and experiential determinants that will contribute to the nature, course, and prognosis of that illness. As noted, for a person at risk for Schizophrenia, a schizotypal constitution may provide a predisposing substrate in which an early brain injury might produce the full schizophrenic syndrome. Moreover, the severity of a brain insult could potentially determine how responsive the individual might be to conventional treatments and how debilitating the illness is. For example, schizophrenics who show evidence of volume loss in their brain also show impaired performance on neuropsychological tests and only a partial response to antipsychotic medication (Weinberger, 1987). Thus, the specific ways in which constitutional and experiential factors interact for a particular individual theoretically may result in differences in both the degree of vulnerability and the severity of the resulting illness.

THE CORTICOLIMBIC SYSTEM

There are several aspects of human behavior mediated by the corticolimbic system that are abnormal in Schizophrenia.

Personality and the Symptoms of Schizophrenia

In evolving a developmental psychopathology of the mental disorders, it is necessary to consider how the risk factors for each may alter circuitry. To do this, it is necessary to understand the mechanisms through which various types of human behavior are integrated within the central nervous system. MacLean (1990) has suggested that a careful analysis of psychiatric disorders can potentially help us to identify such mechanisms. Toward this end, an initial step is to consider what brain regions can be reasonably implicated in the generation of a particular syndrome, an approach that has been applied to the study of Schizophrenia (Benes, 1993a, 1993b).

The symptoms of Schizophrenia typically involve changes of emotion, motivation, attentional responses, sociability, and reasoning. These same general categories of behavior are also affected in Bipolar Disorder, but there are significant differences in their phenotypic expression. In a broad sense, the behaviors disturbed in Schizophrenia and Bipolar Disorder are also central features of personality, which is defined by *Dorland's Medical Dictionary* (1974, p. 1170) as “the total reaction of an individual to the

surrounding environment.” It has been suggested that alterations of temperament can be induced in both monkeys (Ward, 1948a, 1948b) and humans (Tow & Whitty, 1953) following surgical ablations of certain corticolimbic regions, such as the anterior cingulate cortex. In the discussion that follows, several features of personality, known to be abnormal in psychotic disorders, are considered in relation to the anterior cingulate cortex and other corticolimbic areas with which it is extensively connected.

Affectivity

A hallmark feature of Schizophrenia, particularly when it takes a chronic course, is a progressive disappearance of affect (Bleuler, 1952). Schizophrenics characteristically show a facial expression that lacks emotion, a reflection of their inability to generate appropriate affective responses to surrounding events. In some cases, an affective response is noted but is inappropriate; in others, it may be “shallow.” In general, schizophrenics are unable to tolerate a high degree of emotion expressed by others around them; such an occurrence seems to predispose them to relapse (Barrelet, Ferrero, Szogethy, Giddey, & Pellizzer, 1990).

Emotional conditioning and anxiety responses are behaviors that first became apparent in mammals. They are probably mediated in part by phylogenetically primitive brain regions such as the brain stem reticular formation, hypothalamus, septal nuclei, and amygdala. This would help to account for the suggestion that fearfulness in cats appears to be modulated by these same limbic structures (Adamec, 1992). The participation of the amygdala in emotional responses was first highlighted by the work of Kluver and Bucy (1937), in which temporal lobe lesions in monkeys were associated with “psychic blindness,” whereby events seem to lose their emotional implications.

Although the brain mechanisms associated with emotion continued to elude study by the neuroscience community, the past 10 years has brought a renaissance of interest in this area. For example, it is now well recognized that the amygdala plays a central role in fear conditioning (Ledoux, 2000a, 2000b). Many aspects of these responses involve the subcortical connectivity of the amygdala; however, the participation of the hippocampus is probably equally critical. Indeed, oscillatory rhythms typically associated with normal hippocampal activity have also been recorded from the amygdala (Pare & Collins, 2000). This is not surprising given the extensive connectivity that exists between these latter two regions. It is becoming increasingly clear that the learning and memory normally associated with hippocampal function may be driven, at least in part, by discharges

of activity from the basolateral nuclear complex. Equally important is the connectivity between these two regions and the anterior cingulate cortex. Together they constitute the great limbic lobe delineated by Broca (1878).

Selective Attention

Bleuler (1952) was perhaps the first to emphasize that schizophrenics have great difficulty selectively focusing; this is reflected in their low scores on the continuous performance task (CPT; Kornetsky & Orzack, 1978). This loss of selective attention in Schizophrenia may be due to a defective central filtering mechanism (Detre & Jarecki, 1971) that gives rise to overinclusive thinking (Cameron, 1938; Payne & Friedlander, 1962). Typically, patients with Schizophrenia cannot distinguish relevant from irrelevant objects in their perceptual field, a defect that seems to arise early in the course of the illness and one that might involve an impairment of inhibitory mechanisms (McGhie & Chapman, 1961; see later discussion). Some believe that the cingulate and parietal cortices may cooperate in the performance of directed attention (Mesulam, 1983). In monkeys, lesions of the anterior cingulate cortex bilaterally have been associated with neglect of surrounding objects and even cage mates (Glees, Cole, Whitty, & Cairns, 1950). A similar syndrome has been observed in cats with cingulate ablations (Kennard, 1955). In humans with bilateral infarction of the cingulate gyrus, a lack of attentiveness to the surrounding environment has been observed (Laplante, Degos, Baulac, & Gray, 1981). Moreover, a recent cerebral blood flow study reported that human subjects show a marked increase of activity in the anterior cingulate region during performance of a Stroop attentional conflict paradigm (Pardo, Pardo, Janer, & Raichle, 1990). In schizophrenic subjects, a slower response to targets in the right, but not the left, visual fields, and attentional deficits similar to those following left hemispheric lesions were also noted (Posner, Early, Reisman, Pardo, & Dhawan, 1988).

It is noteworthy that abnormalities of smooth-pursuit eye movements have been found in schizophrenics and in their first-degree relatives and could reflect a latent trait for this disorder (Holzman et al., 1988). The neglect occurring with lesions of the cingulate cortex is thought to involve alterations in the relationship of the cingulate region with frontal eye field 8 (Belaydier & Maugierre, 1980), but this may be an indirect effect mediated through connections of this region with the prefrontal and inferior parietal areas. Nevertheless, the smooth-pursuit abnormalities seen in schizophrenic subjects may reflect a role of frontal eye field 8 in the attentional deficits also seen in patients with

this disorder. Patients with unilateral neglect syndromes arising from lesions of the frontal or parietal regions also show some emotional disturbances, and these defects are consistent with a “parallelism in the integrity of attention and emotion” (Mesulam & Geschwind, 1978, p. 252), a concept that Bleuler first suggested to be pertinent to our understanding of Schizophrenia.

Motivation

A defect of motivation is another core feature of Schizophrenia. A model for understanding loss of motivation and interest comes from the description of massive frontal lobe lesions resulting in the apathico-akinetic-abulic syndrome (Luria, 1973). As in Schizophrenia, individuals with such lesions are passive, lack desires, and have poor hygiene (Luria, 1973). In some studies, schizophrenics who failed to activate cerebral blood flow in the dorsolateral prefrontal cortex also performed poorly on the Wisconsin Card Sort, a functional marker for this area (Weinberger, Berman, & Zec, 1986), and the differences did not appear to be related to either poor attention or global cortical dysfunction (Berman, Zec, & Weinberger, 1986). Using near-infrared imaging, studies of executive function using the Stroop interference paradigm have demonstrated significant differences between children and adults in the prefrontal area (Schroeter, Zysset, Wahl, & von Cramon, 2004). Presumably, significant changes are occurring during adolescence, when Schizophrenia typically begins. Accordingly, the timing of such developmental changes could play a critical role in determining the nature of the clinical deficits noted in patients with Schizophrenia.

Bleuler (1952) may have been the first to suspect a link between affect and motivation. He wrote, “The will, a resultant of all the various affective and associative processes, is of course disturbed in a number of ways, but above all by the breakdown of the emotions” (p. 70). The interaction of motivation and affect in humans is illustrated by a distinctive syndrome called akinetic mutism, seen in patients with bilateral destructive lesions of the anterior cingulate cortex (Barris & Schumann, 1953). Acute infarctions of this type are associated with an inability to move or speak, as well as considerable negativism. This is quite similar to the catatonic state in which muteness, lack of movement, and negativism are also observed. Patients who had akinetic mutism arising from bilateral occlusion of the anterior cerebral arteries and who later recovered have described a sudden loss of the experience of affect and a concomitant absence of the will to move (Damasio & Van Hoesen, 1983). A similar concurrence of defects in

motivation and emotional experience, as seen in Schizophrenia, could arise from a disturbance in communication between the dorsolateral prefrontal area and the anterior cingulate cortex. A recent imaging study has demonstrated that there is a reduced correlation of structural parameters between the cingulate gyrus and prefrontal area (Mittleman, Shihabuddin, Brickman, Hazlett, & Buchsbaum, 2005), a change that implies that there is probably an imbalance in the functional interactions between these two regions in Schizophrenia.

Sociability

Schizophrenics have great difficulty engaging in relationships with other people, and this results in marked isolation. It is no surprise that these patients rarely marry and raise families. Female schizophrenics, in general, are unable to nurture their children. The inability of these patients to relate to others and share empathetically in their feeling states is probably central to their impaired social skills, both within family units and outside them.

The cingulate gyrus has been implicated in the mediation of interpersonal relations because ablations of this region are associated with a loss of maternal activities, such as nursing, nest building, and retrieval of the young (Slotnick, 1967; Stamm, 1955). It has been suggested that separation calls and play activities, key features associated with the appearance of social interaction, may have emerged in parallel with the development of the cingulate gyrus during the phylogenetic progression of reptiles into mammals (MacLean, 1985). MacLean has suggested that separation calls that also first appeared in mammals may be mediated by the cingulate gyrus. In support of this, vocalizations can be elicited by stimulation of the anterior cingulate region in monkeys (Smith, 1945). More extensive ablations that also include the medial prefrontal cortex and the subcallosal and preseptal cingulate cortices result in a complete loss of spontaneous isolation calls (MacLean, 1985).

If the cingulate gyrus plays a role in social interactions, it is possible that the unrelatedness and poor social skills typically observed in Schizophrenia may also be related, at least in part, to associated defects in motivation and attentiveness. It seems likely, however, that lack of interest in and neglect of one's surroundings might also contribute to diminished interactiveness.

Logical Processing

One of the most significant core defects in Schizophrenia is a formal thought disorder, in which there are illogical sequences of unrelated concepts. Attempts have been made

to characterize the nature of the defective thinking found in schizophrenic patients. Toward this end, methodologies for evaluating the central processing of incoming information have been developed to study thought disorder in these patients. One such study characterized the abnormalities of central integration in schizophrenics as involving serial processing of information, but with a limited channel capacity (Callaway & Naghdi, 1982). It has also been found that, when an informational target stimulus is followed at varying intervals by a noninformational masking stimulus, a temporal delay in a two-choice forced discrimination task is observed in schizophrenics (Saccuzzo & Braff, 1986). This information-processing defect appears to be trait-dependent, rather than an epiphenomenon of the psychotic state, because individuals with the schizotypal personality profile also show it (Saccuzzo & Braff, 1986). This latter finding implies that the thought disorder seen in Schizophrenia might be a genetically transmitted attribute, perhaps one arising from a specific alteration in neural circuitry. The left inferior parietal lobe has been implicated in the construction of logical grammatical relationships, and patients with focal left inferior parietal lesions demonstrate a marked impairment in the ability to formulate thoughts that involve the communication of relationships among ideas (Luria, 1973). It is noteworthy that neurons in monkeys' posterior parietal cortex are activated by hand-eye coordinated movements, particularly when desirable objects that can satisfy thirst or hunger are used (Mountcastle, Lynch, Georgopoulos, Sakata, & Acuna, 1975). This motivationally driven response is believed to require not only limbic connections with the parietal region but also an attentional component (Mesulam & Geschwind, 1978). Consistent with this proposal, the inferior parietal region has extensive connections with the anterior cingulate cortex and the presubiculum (E. G. Jones & Powell, 1970; Pandya & Kuypers, 1969; Petras, 1971; Seltzer & Pandya, 1978; Seltzer & Van Hoesen, 1979). Thus, interactions of this type may provide at least part of the limbic component to inferior parietal responses to desirable objects.

Luria (1973) emphasized the role of the left (dominant) inferior parietal region in the construction of logical grammatical relationships; he also described unilateral neglect syndromes in patients with right-sided posterior parietal lesions. These patients do not attend to left extracorporeal space, but they also show a peculiar inability to perceive their defects. The failure to perceive one's defects is commonly seen in schizophrenics, who are unable to notice that a listener is unable to comprehend what they are saying. The simultaneous occurrence of illogical thinking and neg-

lect in Schizophrenia is consistent with the idea that both the left and the right inferior parietal areas might be dysfunctional in this disorder. As noted earlier, neglect of the surrounding environment occurs with cingulate lesions, and the coincidence of attentional problems and disturbances of thinking could reflect the extensive connections between the anterior cingulate and inferior parietal cortices.

Corticolimbic Involvement in Disorders of Thought, Perception, Mood, and Anxiety

Based on the discussion of the symptoms of Schizophrenia and the functions of several corticolimbic regions, it has been suggested that the anterior cingulate cortex as well as the dorsolateral prefrontal region, inferior parietal lobe, and hippocampal formation with which it connects, may be of central importance to the symptomatology, and possibly even the etiology, of Schizophrenia. The functions collectively subsumed by these regions cover a broad range of behaviors, including affect, attention, motivation, social behavior, cognition, and the influence of stress on the modulation of these behaviors. It is relevant to this discussion to consider whether other psychiatric disorders may possibly involve alterations in similar cortical regions. In bipolar mood disorder, as mania alternates with depression, patients may show increases or decreases of emotional expression, motivation, attention, interpersonal relations, and thinking. On the one hand, manic individuals typically show rapid thinking and a flight of ideas from one concept to another, frequently of a grandiose nature. On the other hand, patients with depression show thinking that is slowed and often fixated on only certain ideas, usually of a self-deprecatory nature. Opposite disturbances in social behavior also occur in patients with affective disorders, with manic patients being inappropriately interactive or even intrusive, but depressed patients being very withdrawn or isolative. In considering the brain areas that might play a role in these mood disturbances, it is noteworthy that chronically depressed patients show improvement of their mood following bilateral anterior cingulotomy (Ballantine, Cassidy, Flanagan, & Marino, 1967; Tow & Whitty, 1953), a procedure that does not produce deficits in, and may even improve, overall cognitive function (Long, Pueschel, & Hunter, 1978).

Other psychiatric syndromes, such as Panic Disorder and phobias, frequently occur comorbidly with depression. Individuals with phobias have been found to have been prone to separation anxiety as children, and many were branded as school phobics during childhood (Klein, Zitrin, & Woerner, 1978). The suggestion by MacLean (1985) that

the cingulate area might mediate separation behaviors (see earlier discussion) could provide a theoretical basis for understanding this syndrome, which also responds well to treatment with antidepressant medication. Another syndrome occurring comorbidly with depression is Panic Disorder, characterized by episodes of acute anxiety in which an individual experiences shortness of breath, tachycardia, profuse sweating, and pallor in response to an irrational perception of impending doom. Because the amygdala (Davis, 2000) and cingulate cortex (Anand & Dua, 1956; Kaada, Pribram, & Epstein, 1949) are involved in the regulation of autonomic visceromotor responses, it is possible that these regions, and/or areas with which they connect, could participate in the generation of panic attacks as well.

“Le Grande Lobe Limbique”

In parallel with the first appearance of mammalian features in vertebrates, Broca (1878) noted that a “limbic lobe,” consisting of the septal nuclei, amygdala, hippocampus, parahippocampal (entorhinal) cortex, and cingulate gyrus, appeared along the midsagittal plane of virtually all mammalian forms (Figure 5.2). In 1947, Paul MacLean extended the concept of the limbic system by suggesting that

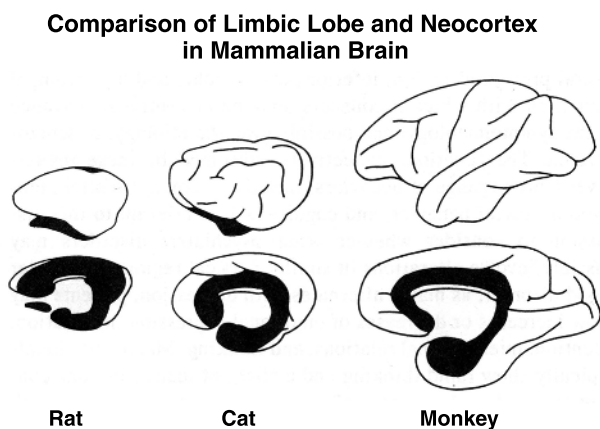

Figure 5.2 The appearance of the brain in the rat, cat, and monkey, shown both in a lateral (above) and a midsagittal (below) view. All three brains show a contiguous loop (black) of limbic structures (including the cingulate gyrus, parahippocampal gyrus, and amygdala) that has remained remarkably similar during phylogenesis. This so-called limbic lobe is surrounded, above and laterally, by neocortex that has shown a progressive increase during phylogeny. *Source:* From “Studies on Limbic System (Visceral Brain) and Their Bearing on Psychosomatic Problems” (pp. 101–125), by P. D. MacLean, (1954). In *Recent Developments in Psychosomatic Medicine*, E. Wittkower and C. R. Klerghorn (Eds.), Philadelphia: Lippincott.

the human brain is organized into a “triune” system consisting of a reptilian brain (brain stem and other subcortical structures), an old mammalian brain (amygdala and hippocampus) that is responsible for simple feelings and emotional expression, and a new mammalian brain (neocortex) that represents a “voice of reason” in modulating emotional stimuli (MacLean, 1954, 1990).

As noted by MacLean (1985), the elaboration of this limbic lobe coincided with the appearance of audition, vocalization, maternal nurturance, and separation calls by the young, suggesting that the integration of visceral responses with cortically mediated behaviors might have facilitated the protection of young offspring. These behaviors require all three components of the so-called triune brain. Accordingly, the evolutionary trend toward developing more elaborate behaviors has involved a corresponding increase in both the amount and complexity of ties between the brain stem and old mammalian components of the limbic system. Within the spectrum of mammalian forms, there has been a striking increase in the relative proportion of neocortex to Broca’s limbic lobe. Figure 5.2 shows a comparison of the limbic lobe in rat, cat, and monkey brain (MacLean, 1954). It is evident from the figure that there has been a progressive increase in the volume of the neocortex surrounding the cingulate and parahippocampal gyri. In primates and humans, this has been accompanied by the most extensive elaboration of connectivity between associative cortical regions, such as the cingulate region and the hippocampal formation, with the subcortical limbic system (Figure 5.3). The brain does not have a specific mechanism for deleting phylogenetically older circuits and instead has integrated older circuits with newly acquired ones within the corticolimbic system. As a result, there has been a progressive increase in the integration of higher cognitive processes with visceral and instinctual behaviors mediated through subcortical limbic structures. In the human brain, this additive tendency that has occurred during phylogeny has probably been adaptive because it is doubtful that the human species could have survived with cortically driven logical planning and volition without the drive that comes from limbically driven emotions.

By examining the regions that compose the corticolimbic system and their interconnections, it can be appreciated that defective integration in one or several of these areas could give rise to abnormalities in the cortical integration of emotional experience, with functions integrated primarily at the neocortical level, such as volition and logic. A psychopathological process—Schizophrenia, for example—that impacts on one or several corticolimbic regions

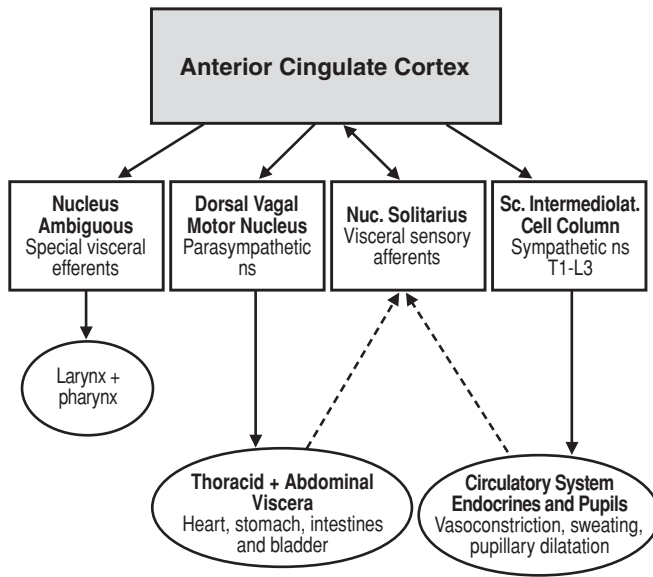

Figure 5.3 The anterior cingulate cortex and its corticobulbar and corticospinal connections, which are involved in the mediation of visceral motor and sensory responses. The anterior cingulate cortex plays a unique role in the integration of affective experience with higher cognitive function via its extensive interactions with both brain stem and spinal centers involved in autonomic processing. Corticobulbar fibers, originating in the anterior cingulate region, project to the nucleus ambiguus and the dorsal vagal motor nucleus and the preganglionic sympathetic fibers of the intermediolateral cell column to influence the outflow of activity to special visceral efferent muscles (e.g., larynx and pharynx), thoracic and abdominal viscera (e.g., the heart, esophagus, stomach, intestines, and bladder), and blood vessels and sweat glands. Extensive connections of the anterior cingulate region with the nucleus solitarius probably influence the inflow of sensory information from all viscera of the body.

could potentially give rise to a broad variety of symptoms that encompass the emotional and cognitive spheres.

The Anatomy of the Corticolimbic System

The corticolimbic system consists of the cingulate gyrus, hippocampal formation, and amygdaloid complex. All of these structures can be found on the midsagittal surface of the mammalian brain, and they interact extensively in the mediation of emotion, attention, and learning.

The Anterior Cingulate Cortex Integrates Visceral Responses with Cognition

Papez (1937) was the first to postulate that the cingulate gyrus may play a central role in the integration of emotional experience with cognition because it not only has extensive connections with the limbic system, but it also has

rich reciprocal connectivity with other associative cortical regions involved in higher cognitive functions. These patterns of connectivity lay the groundwork for the concurrence of visceral responses with thinking. As shown in Figure 5.3, autonomic responses can be altered by either stimulation or ablation of the anterior cingulate cortex. With electrical stimulation of this region in primates, visceromotor responses such as eyelid opening, pupillary dilation, respiratory movements, cardiovascular changes, and piloerection (Anand & Dua, 1956; Kaada et al., 1949; Smith, 1945) have been induced. Notably, changes in facial expression (Smith, 1945) and motor arrest (Dunsmore & Lennox, 1950; Smith, 1945) have also been observed. Extensive surgical ablation of the anterior cingulate cortex, on the other hand, has resulted in a decrease of emotional responsiveness (Ward, 1948a). Personality changes characterized by either inappropriate purring or growling without provocation have been observed in cats with cingulate lesions (Kennard, 1955); in humans, bilateral infarction of the cingulate gyrus has been associated with increased docility and indifference (Laplane et al., 1981). Interestingly, an inability to either express or experience emotion has been described in patients with bilateral cingulate gyrus infarction (Damasio & Van Hoesen, 1983). The decrease in emotional responsiveness seen in cingulotomized patients bears some resemblance to the flat affect seen in schizophrenics.

The anterior cingulate region plays a pivotal role in the integration of the more primitive portions of the limbic system with the evolving neocortex. This region has extensive reciprocal connections with several different cortical areas that include the dorsolateral prefrontal region, the hippocampal formation, and the inferior parietal lobe (E. G. Jones & Powell, 1970; Pandya & Kuypers, 1969; Petras, 1971; Seltzer & Pandya, 1978; Seltzer & Van Hoesen, 1979). Of great importance, the anterior cingulate region also has both afferent and efferent connections with nuclear groups that mediate autonomic functions (Figure 5.3), such as the periaqueductal gray (Beckstead, 1976; Domesick, 1969; Hurley, Herbert, Moga, & Saper, 1991; Wyss & Sripanidkulchai, 1984), the nucleus solitarius, the dorsal motor nucleus of the vagus (Hurley et al., 1991; Terberry & Neafsey, 1983, 1987; Van der Kooy, McGinty, Koda, Gerfen, & Bloom, 1982), and preganglionic sympathetic neurons in the intermediolateral cell column of the thoracic spinal cord (Hurley et al., 1991). Accordingly, the anterior cingulate cortex interacts directly with centers that mediate both viscerosensory and visceromotor responses in the periphery relationships that are believed to be fundamental to its role in integrating emotional

responses at the cortical level (Neafsey, Terreberry, Hurley, Ruit, & Fryszak, 1993). Either ablation (Kennard, 1955; Laplane et al., 1981; Ward, 1948a) or stimulation (Anand & Dua, 1956; Kaada, 1960; Kaada et al., 1949; Smith, 1945) of the anterior cingulate cortex results in both autonomic and affective changes. In humans with documented seizure activity arising from the cingulate cortex (Devinsky & Luciano, 1993), emotional stimulation is a frequent precipitant of ictal activity (Mazars, 1970). The majority of such patients exhibit limbically related features such as temper tantrums and fixed psychoses. In one reported case, a child with cingulate seizures was noted to run toward her mother during ictal episodes (Geier et al., 1977), a manifestation consistent with the proposed role of the cingulate cortex in mammalian separation behaviors (MacLean, 1985). Thus, the various corticolimbic connections of anterior cingulate cortex and the behavioral manifestations associated with its lesions support the idea that this region may play a particularly central role in the integration of limbic functions with higher cognitive processing (Papez, 1937).

The cingulate cortex is connected with the dorsolateral prefrontal area, frontal eye field 8, the inferior parietal lobe, and the hippocampal formation. The entorhinal region provides a key relay of information from the prefrontal area to the hippocampal formation. The prefrontal, anterior cingulate, and entorhinal cortices receive a rich supply of dopamine afferents from the midbrain ventral tegmental area (Lindvall & Bjorklund, 1984). Some of the areas are phylogenetically newer cortical regions (e.g., the dorsolateral prefrontal and inferior parietal regions) and are most extensively developed in the human brain. In contrast, the hippocampal formation is phylogenetically the oldest cortical region that first appeared in a rudimentary form in reptiles (Ulinski, 1990). The cingulate and entorhinal cortices are transitional limbic cortices that first appeared in early mammals and provide a link between the hippocampal formation and the neocortical regions (e.g., the dorsolateral prefrontal and inferior parietal regions) that are particularly well developed in humans.

The Hippocampus and Learning Mechanisms

The hippocampal formation is the oldest portion of the cortex that first appeared in reptiles. It consists of several subregions: the area dentata, sectors CA4-1, the subiculum, and the presubiculum (see Rosene & Van Hoesen, 1987). In the mammalian brain, the hippocampus has retained a characteristic three-layered organization that can be recognized using low-power optics. When examined at higher powers, there are actually five different layers distinguishable in the CA subfields. These include the stratum molec-

ulare, stratum radiatum, stratum pyramidale, stratum oriens, and alveus. The stratum pyramidale contains the majority of neuronal cell bodies; the other four laminae principally contain both efferent and afferent fiber systems. As shown in Figure 5.2, the so-called trisynaptic pathway consists of (1) perforant fibers from the entorhinal cortex that project to the outer molecular layer of the area dentata, (2) mossy fibers from the granule cells of the area dentata that project to the stratum radiatum of CA3, and (3) Schaffer collaterals of pyramidal cells in CA3 that project to the stratum radiatum of CA1.

The Amygdala and Emotionally Stimulated Learning

The amygdala is a complex corticolimbic region that lies at the temporal pole of the mammalian brain. Considered by some to be an "arbitrarily" defined set of cell groups, there are nevertheless subdivisions of this region that can be distinguished by their characteristic architecture, embryogenesis, neurotransmitter profiles, connectivity, and functional roles (Swanson & Petrovich, 1998). These include an olfactory part (central and main) that projects topographically to other regions involved in reproductive, defensive, and ingestive behavior systems in the hypothalamus, a central nucleus (CEA) that projects to autonomic centers in the brain stem, and the frontotemporal system that projects to the striatum, nucleus accumbens, hippocampus, and cortex. The latter system is distinguished from the other, more primitive components of the amygdala by its being a ventral extension of the claustrum; on this basis, it is considered to be a derivative of the frontal and temporal cortex. Whereas the central subdivisions of the amygdala have projection neurons that employ gamma-amino butyric acid (GABA) as a neurotransmitter, thus establishing their homology with the basal ganglia, the projection neurons of the basolateral complex, like those of the cortex, use glutamate as a transmitter.

The basolateral nuclear complex appears to play a complex role in associative learning and attention (Gallagher & Holland, 1994). This region regulates sensorimotor gating of the acoustic startle response (Wan & Swerdlow, 1997) and contributes to fear conditioning, possibly through a mechanism involving its GABAergic interneurons (Stutzmann & LeDoux, 1999). In this latter regard, both the central and basolateral subdivisions seem to contribute to this response. For example, lesions of the central nucleus resulted in a reduction in the suppression of behavior elicited by a conditioned fear stimulus, but the animals were able to direct their actions to avoid further presentations of this aversive stimulus (Killcross, Robbins, & Everitt, 1997). In this same study, rats with lesions of the basolateral complex

were unable to avoid the conditioned aversive stimulus by their choice behavior, but exhibited normal conditioned suppression to the stimulus. Thus, it appears that discrete subdivisions of this nucleus probably contribute different components to an integrated emotional response (Killcross et al., 1997) and with recall of emotional information (Cahill & McGaugh, 1998). Although the amygdala is probably not the actual site for long-term storage of explicit or declarative memory, it appears to influence memory-storage mechanisms in other brain regions, such as the hippocampus and neocortex (Killcross et al., 1997). In one case report where there was selective bilateral damage to the amygdala, the subject was unable to acquire conditioned autonomic responses to visual or auditory stimuli, although declarative facts could be successfully paired with unconditioned stimuli (Bechara et al., 1995). The amygdala is probably involved in aversive conditioning, and the hippocampus seems to play a role in contextual associative learning (Selden, Everitt, Jarrard, & Robbins, 1991). Some authors believe the basolateral complex of the amygdala contributes to the plasticity associated with the encoding of Pavlovian fear conditioning (Fanselow & LeDoux, 1999) and may help to guide goal-directed behavior (Schoenbaum, Chiba, & Gallagher, 1998). Rats with lesions of the basolateral complex are insensitive to postconditioning changes in the value of a reinforcer, and this second-order effect is believed to reflect the presence of a positive incentive value for a conditioned stimulus (Hatfield, Han, Conley, Gallagher, & Holland, 1996).

Like the hippocampus, the cingulate cortex also works cooperatively with the basolateral complex in mediating conditioned memory. For example, rabbits with lesions of the amygdala show a decrease of discriminative avoidance learning, and this effect is believed to involve plasticity of cingulothalamic interactions (Poremba & Gabriel, 1997). Overall, the amygdala appears to be necessary for the acquisition, but not the maintenance, of associative learning that occurs when fear is used as a conditioned stimulus.

Stress appears to play a central role in modulating the activity of the basolateral nucleus of the amygdala and influences its memory-modulating systems in relation to emotionally arousing events (for a review, see Cahill & McGaugh, 1998). Both norepinephrine and dopamine show an increased release in the amygdala of stressed animals (for a review, see Stanford, 1993). For the dopamine system, acute stress is associated with a selective increase in the release of this transmitter from the medial prefrontal cortex (Thierry, Tassin, Blanc, & Glowinski, 1976); however, with more prolonged stress, the nucleus accumbens shows a similar increase (Bannon, Wolf, & Roth, 1983; Roth, Tam, Ida, Yang, & Deutch, 1988). More recent work has demon-

strated that the amygdala plays an important role in regulating the response of the medial prefrontal dopamine system to stress (Goldstein, Rasmusson, Bunney, & Roth, 1996). Whether this effect is mediated directly through the basolateral projections to the cortex or occurs indirectly via projections to the centromedian nucleus is not known. The centromedian nucleus projects to the periaqueductal gray (Hopkins & Holstege, 1978), a central relay zone for the regulation of stress-related behaviors such as freezing (LeDoux, Iwata, Cicchetti, & Reis, 1988) that involve brain stem and spinal nuclei that control the larynx, pharynx, and respiratory musculature (Holstege, Tan, Van Ham, & Bos, 1984; Jurgens & Pratt, 1979).

The connections between the amygdaloid complex and the anterior cingulate cortex may be particularly important to understanding the pathophysiology of neuropsychiatric disorders. Layer II of the anterior cingulate region, where a variety of anomalies have been detected in Schizophrenia (see earlier discussion), receives a "massive" input from the basolateral complex of the amygdala (Van Hoesen, Morecraft, & Vogt, 1993). In a series of postmortem studies, an increase of vertical fibers was found in layer II of the anterior cingulate cortex (Benes, Majocha, Bird, & Marotta, 1987; Benes, Sorensen, Vincent, Bird, & Sathi, 1992) and the entorhinal region (Longson, Deakin, & Benes, 1996), but not the prefrontal cortex. Because this latter region does not receive an appreciable input from the amygdala (Van Hoesen et al., 1993), it seemed possible that those fibers showing an increase in the anterior cingulate area might originate in a region that projects to the latter, but not the former. It is intriguing to note that intense glutamate-immunoreactivity localized to vertical axons in superficial layers of the anterior cingulate (Benes, Sorensen, et al., 1992) and entorhinal regions (Longson et al., 1996) has also been described in projection neurons of the basolateral complex (McDonald et al., 1989). Although a direct link between these two neuronal compartments cannot be established with evidence of this type, it seems likely that the basolateral nucleus and the anterior cingulate region may play a particularly important role in the pathophysiology of Schizophrenia and other neuropsychiatric disorders. The hippocampus has also been found to have abnormalities in Schizophrenia and Bipolar Disorder, particularly in sectors CA3 and CA2 (Benes, 2000).

DEVELOPMENT OF THE CORTICOLIMBIC SYSTEM

In any study of the corticolimbic system of the schizophrenic brain, the six-layered organization of the cortex is

relevant to consider because alterations that occur in superficial laminae would be more likely to impact on higher cognitive processes. Also noteworthy is the fact that layer II in the anterior cingulate cortex (Van Hoesen et al., 1993) and sectors CA3 and CA2 (Benes & Berretta, 2000) receive significant projections from the basolateral amygdala. As discussed next, these same loci show a variety of abnormalities in both Schizophrenia and Bipolar Disorder. This suggests that the specific connectivity that exists in the corticolimbic system may contribute in specific ways to the pathophysiology of psychotic disorders.

Let's now consider the manner in which components of the corticolimbic system undergo ontogenetic development during pre- and postnatal life. The discussion that follows considers the ontogenesis of the hippocampal formation, followed by the neocortex. The ingrowth of afferents to the cortex and myelination of the cortex are discussed. Finally, the sequential changes that occur for both intrinsic and extrinsic transmitters of the cortex are described. The developmental of the human brain occurs at many different levels, with some that can be observed grossly and others that require sophisticated biochemical and microscopic approaches.

Gyral Development

The development of the cerebral cortex occurs at different rates that, to some extent, reflect phylogeny. There is a gradual tendency for limbic cortical areas to begin to appear during early gestation. For example, at 16 to 19 weeks of embryogenesis, the cingulate gyrus can be distinguished, but this occurs long before the parahippocampal gyrus and hippocampal formation have become discernible in the medial temporal lobe at weeks 20 to 23 (Gilles, 1983). Cortical regions undergo ontogenesis at varying rates that, to some degree, reflect phylogeny (Figure 5.4). The superior and medial frontal gyri (prefrontal regions) do not take on a clear gyral configuration until 24 to 27 weeks of gestational age, and the angular and supramarginal gyri (inferior parietal area) are not distinguished until 28 to 31 weeks (Gilles, 1983). The orbital frontal gyri, which, like the cingulate gyri, are well represented in earlier mammalian forms such as rodents, are among the last to appear.

Perturbations of ontogenesis at various stages of fetal development might be capable of inducing abnormalities in the formation of gyral patterns and corresponding disturbances in specific functional capabilities associated with these regions affected in this way. For example, in subjects with Schizophrenia, obstetrical complications have been found to include viral infections in utero during the second trimester and prolonged labor at the time of birth. It is the-

oretically possible that a viral infection during the second trimester, if it occurs in an individual who carries the susceptibility for Schizophrenia (Jacobsen & Kinney, 1980; Kinney et al., 2000), might result in a phenotypic form of the illness in which there are more apt to be affective or attentional problems, reflecting damage to the anterior cingulate region. On the other hand, another at-risk individual who is exposed to prolonged labor at birth might be more apt to have damage to the dorsolateral prefrontal cortex and experience disturbances in motivation. Differential disturbances associated with ontogenetic development have the potential for explaining, at least in part, the heterogeneous ways in which Schizophrenia presents clinically.

Cytoarchitectural Maturation

Both the hippocampus and cortex undergo distinct changes in their organization and appearance as ontogenes proceeds during the pre- and postnatal periods.

Hippocampus

The hippocampal formation of the human brain is a very complex structure composed of several different subsidiary regions, including the area dentata, the hippocampus proper, the subicular complex, and the entorhinal cortex (Stanfield & Cowan, 1988). The process by which it develops involves a carefully timed sequence of events, although the period during which the sequential changes occur may differ for various mammalian species. For example, in rats, the cells of the regio superior (CA1-CA2) appear during the last half of gestation (Angevine, 1965; Stanfield & Cowan, 1988); in monkeys, they appear during the first half (Rakic & Nowakowski, 1981). There is also a general tendency for neurons of the hippocampus to be generated by mitotic proliferation of precursor elements within a zone closely apposed to the ventricular surface. When a given cell has completed its mitotic proliferation, it begins to migrate upward and eventually assumes its proper position in an "inside-out" progression. This latter process occurs for the hippocampus proper, the subicular complex, and the entorhinal cortex. For the area dentata, however, the disposition of this subregion in the hippocampal formation is such that the cells migrate in an "outside-in" manner. Thus, the direction of migration occurs relative to where the proliferative epithelial zone has generated the cells. Another developmental gradient occurs along the axis lying between the entorhinal cortex and the area dentata (Stanfield & Cowan, 1988). Neurons along the ends of this so-called rhinodentate axis develop earlier; cells in the center (subicular complex and hippocampus proper) appear later.

Development of Gyral Patterns in Utero:

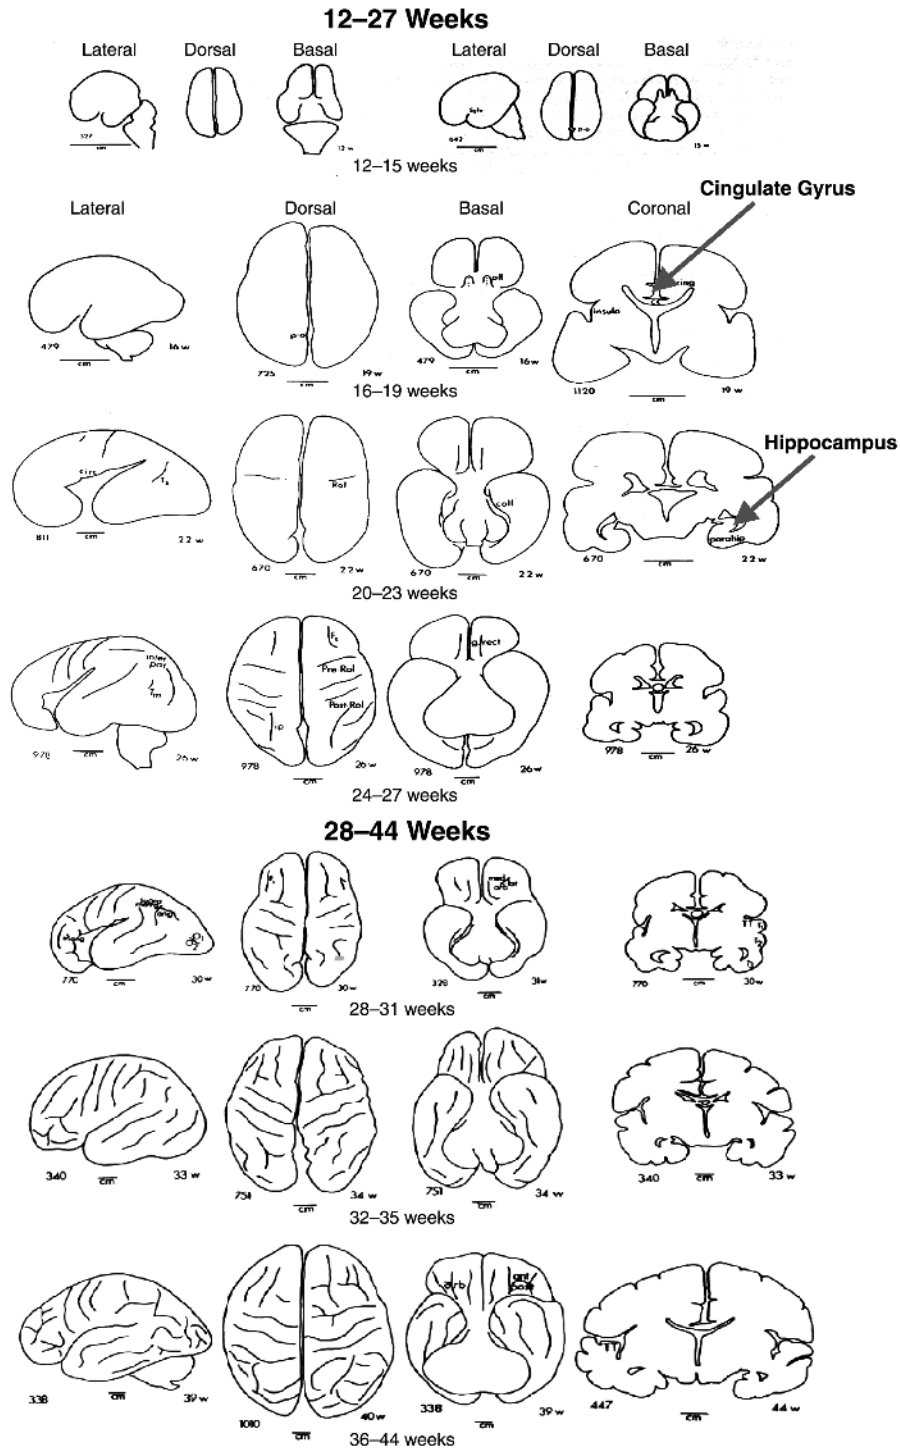

Figure 5.4 A comparison of gyral patterns in the human brain during the second and third trimesters. During the second trimester, there are very few gyri in evidence, with the exception of the cingulate gyrus that appears between 16 and 19 weeks prenatally. The hippocampal gyrus appears somewhat later, between 20 and 23 weeks prenatally. During the third trimester, the number of gyri shows a dramatic increase, especially in the prefrontal area and the superior marginal gyrus. Obstetrical complications that occur during the second trimester might tend to disrupt the normal development of limbic lobe structures, such as cingulate cortex and hippocampus, whereas during the third trimester, the prefrontal cortex might be more affected. The timing of such an insult during prenatal development could influence the types of functions that are disrupted later during the postnatal period in individuals who carry susceptibility genes for a disorder such as Schizophrenia. *Source: The Developing Human Brain: Growth and Epidemiologic Neuropathology.* Gilles, F. H., Leviton, A., and Dooling, E. C. (Eds.), John Wright. PSG Inc. Boston, 1983.

The development of the area dentata may continue well beyond birth. In rats, for example, the numbers of dentate granule cells seem to increase during both the preadult weanling and adult periods (Bayer, Yackel, & Puri, 1982), and the cells arising postnatally are thought to originate from mitotic neuroblasts (Kaplan & Bell, 1984). These newly generated granule cells of the area dentata are thought to give rise to axons that project into subfields CA3 and CA4 of the hippocampus (Stanfield & Trice, 1988). Evidence for postnatal granule cell increases has not been found in rhesus monkeys (Eckenhoff & Rakic, 1988); however, there have not, as yet, been any studies to determine whether similar postnatal changes may occur in the area dentata of the human brain. Thus, it is difficult to know whether postnatal neurogenesis might play a role in human maturation.

Parallels between the ontogenetic development of the hippocampal formation and its phylogeny in vertebrates have been described. At 8 weeks in utero, the human telencephalon is thought to be comparable to that found in mature amphibians (Hoffman, 1963). At 10 weeks, however, it is similar to that of reptiles (Crosby, 1917) and early mammalian species. In the 8-week-old fetus, rostral levels of the forebrain contain the septal nuclei situated immediately ventral to the fornix and medial frontal cortex; at more caudal levels, the fornix is contiguous with the hippocampus (Rakic & Yakovlev, 1968), also having a medial location. The appearance of limbic cortical structures in the medial forebrain of the human fetus early in prenatal development parallels that of phylogenetically earlier forms lacking neocortical structures. Thus, there are some striking similarities in the anatomical relationships of cortical and limbic forebrain structures found in reptiles, early mammals, and the human fetus. This parallelism underscores the notion that these regions are developmental precursors to transitional cortices (such as the cingulate gyrus) that predate neocortical areas such as the prefrontal and inferior parietal regions.

Cortex

The ontogenesis of all cortical regions follows a carefully timed sequence of events (Poliakov, 1965; Sidman & Rakic, 1973). All cortical neurons are generated along the ventricular surface in the so-called marginal zone and migrate toward the surface after undergoing several mitotic divisions. Poliakov (1965) described five stages of cortical development in the human brain that begin with Stage I at approximately the 7th fetal week, when postmitotic cells begin to move upward. Stage V is the longest period and occurs between the 16th fetal week and the early postnatal

period. During Stage V, postmitotic neuronal cells continue migrating and reach their final destination within the cortical plate. As neurons enter the cortical plate, those destined for more superficial layers arrive later than those that occupy deeper layers and show an inside-out progression (Rakic, 1974). Studies of the motor cortex in humans have shown that by 7 months of gestation, layers V and VI have attained a more advanced degree of development than layers II and III (Marin-Padilla, 1970a; Zilles, Werners, Busching, & Schleicher, 1986). The morphological differentiation of neurons in the various layers mirrors this migratory process, such that large pyramidal neurons with a well-developed dendritic arborization and basket cells (inhibitory interneurons) can be distinguished in deeper layers sooner than in superficial layers (Marin-Padilla, 1970b). By 7.5 months in utero, pyramidal neurons in deeper portions of layer III are first beginning to show differentiation of an apical dendrite extending into layer I; in layers V and VI, these cells already have elaborate dendritic arborizations. During this same interval, incoming fibers from other regions are present in virtually all layers of the cortex. In the months immediately prior to birth, interneurons begin to appear in the deeper portions of layer III; in layers II and outer portions of III they are first beginning to form. By birth, both the second and third laminae contain pyramidal neurons; however, basket cells in layer II are largely absent (Marin-Padilla, 1970b). By 2.5 months postnatally, pyramidal neurons continue to mature, showing a dramatic increase in overall size, the amount of dendritic branching, and the numbers of dendritic spines (Michel & Garey, 1984). Interestingly, layers VI and I (the marginal zone) are the first laminae to appear and differentiate, and layers II and III are the last to form and the latest to mature (Marin-Padilla, 1970a). At birth, cortical layer II in the motor cortex of human brains is still quite immature (Marin-Padilla, 1970b). Changes in gene expression probably play an important role in regulating these events. For example, chemokines, together with gamma interferon, could play a role in promoting the migration of cells during early development and possibly also the elaboration of dendritic processes (Parlato et al., 2001). Later in development, interferons may promote dendrite retraction in the setting of injury (Kim, Beck, Lein, & Higgins, 2002).

As with the primate and human cortex, Bayer and Altman (1991) have reported that an inside-out progression is also observed in the medial prefrontal cortex of rodent brain, a homologue of the anterior cingulate region in primates and humans. Cell migration in this region occurs earlier than it does for the hippocampal formation (Bayer, Altman, & Russo, 1990). This pattern reflects

	Mitosis	Migration	Axons	Dendrites	Synapses	Myelin
1st Trimester	+++	++	+	-	-	-
2nd Trimester	-	+++	++	+	-	-
3rd Trimester	-	+	+++	+++	++	+
Postnatal Period	-	-	+	++	+++	+++

Table 5.1 The time course for mitotic division of precursor cells in the subventricular zone and their migration upward toward the cortical plate, the growth of axons and dendrites, the formation of synaptic connections, and the appearance of myelin sheaths occurs differentially during the first, second, and third trimesters. Synapse formation and myelination both occur most extensively during the postnatal period.

that described earlier for gyral development, where the cingulate gyrus differentiates weeks in advance of the parahippocampal gyrus and hippocampal formation, except that in this instance, it follows a dorsal-to-ventral course (see Table 5.1). Presumably, the analogous timing of events for the prefrontal cortex of the human brain is somewhat different, but its growth and maturation as a gyrus is likely complete by the 2nd year of life. Postnatally, the medial prefrontal cortex of rats shows a progressive expansion of its matrix as the neuropil surrounding neuronal cell bodies increases. The increase of the neuropil occurs in the preweanling period that is roughly equivalent to preadolescence in humans. The increase of the neuropil is probably related to two different events: (1) the ingrowth of fibers from other cortical and subcortical regions and (2) the collateralization of axons from neurons intrinsic to the cortex. These changes also follow an inside-out progression similar to that seen in relation to cell migration. In the medial prefrontal cortex of rat brains, the thickness is not maximal until P20, which marks the beginning of the postweanling period (Vincent, Pabreza, & Benes, 1995), an interval that is roughly equivalent to adolescence in human development.

Beyond the perinatal period, the packing density of neurons in the human cortex decreases dramatically during the 1st year of life (Blinkov & Glezer, 1968). In the dorsolateral prefrontal cortex (Brodman areas 9 and 10), neuronal density continues to decrease until 5 to 7 years of age, although in layer II of some regions, this process may continue until 12 to 15 years of age (Blinkov & Glezer, 1968).

Three- and Six-Layered Cortex

To understand how defects in the corticolimbic system can influence the processing of activity in subcortical regions,

it is useful to examine more closely the cytoarchitectural organization within the cortex of higher mammals. The cortex of reptiles has a simple three-layered organization (Ulinski, 1977); the mammalian neocortex has been expanded into six layers, which can be distinguished from one another according to the density and size of neurons, as well as their morphological appearance. For example, layer I has sparse numbers of relatively small interneurons; layers II, III, V, and VI contain large numbers of projection cells called pyramidal neurons. These cells typically send their axons out of the cortex to other, distal sites. In contrast to the pyramidal cell layers, layer IV contains abundant numbers of excitatory interneurons, called granule cells. Relative to layer IV, the deeper layers V and VI are called infragranular layers and the superficial layers I through III, supragranular layers.

Interestingly, there is a basic dichotomy between the superficial and the deep layers of the mammalian cortex. Pyramidal neurons in layers V and VI project axons primarily to subcortical structures; those in layers II and III send their axons preferentially to other cortical sites (E. G. Jones, 1984). Layer IV receives a rich supply of afferents from the thalamus (White, 1986), and layer I has a large number of incoming associative inputs from other cortical regions (Marin-Padilla, 1984). Thus, these latter two receptive layers reflect this subcortical and cortico-cortical relationship of the other infragranular and supragranular projection layers, respectively. In a very general sense, then, the phylogenetic development of the cortex has involved an expansion from three to six layers, and it is of more than passing interest that the three supragranular layers have a more specific role in processing associative activity and an ever-increasing role in phylogenetically more advanced species, such as primates and humans. The thickness of the supragranular layers is proportional to the amount of associative activity that a particular region mediates. For example, the primary visual cortex has a rudimentary amount of layers I through III; the tertiary visual association area 19 has a well-developed supragranular zone. Supramodal (tertiary) cortical regions such as the cingulate, prefrontal areas, and inferior parietal areas, which are associative in nature, have upper layers that are thicker than the deeper layers. Overall, the marked expansion of the associative cortex that has occurred in relation to phylogenesis of the brain has involved a dramatic increase in supragranular laminar processing.

Myelin Formation

A broadly accepted marker for the functional maturation of the central nervous system is the formation of myelin

sheaths, the insulating covering that surrounds axon shafts. It has long been known that various neural pathways myelinate at different stages of pre- and postnatal development and, for humans, this process has long been thought to continue well after birth, particularly in the prefrontal cortex (Flechsig, 1920; Yakovlev & Lecours, 1967). There is a general tendency, however, for more cephalad structures to myelinate later than those found at more caudal levels of the neuraxis, and for subcortical pathways to myelinate before cortical associational paths (Yakovlev & Lecours, 1967). For example, the medial longitudinal fasciculus, a pathway that is found along the entire extent of the spinal cord and brain stem, begins myelinating as early as week 20 of the gestational period, and the medial lemniscus, a pathway confined to the brain stem, shows similar changes at gestational week 24 (Gilles, Shankle, & Dooling, 1983). In the cerebral hemispheres, the posterior limb of the internal capsule begins myelinating at gestational week 32, but the anterior limb does not show evidence of myelin formation until week 38. Interestingly, proximal portions of the cingulum bundle do not begin to myelinate until gestational weeks 38 to 39 (Gilles et al., 1983). On the other hand, some subcortical relays, such as the fornix and mammillothalamic tract, do not begin to myelinate until gestational weeks 44 and 48, respectively.

Some pathways in the corticolimbic system continue to myelinate until much later in the postnatal period (Benes, 1989; Benes, Turtle, Khan, & Farol, 1994). For example, the superior medullary lamina (Figure 5.5, upper panel), a fiber bundle found along the surface of the parahippocampal gyrus, shows an increase of myelin staining not only during the 1st and 2nd decades of life (Benes, 1989), but even as late as the 5th and 6th decades (Figure 5.5, lower panel; Benes et al., 1994). It is noteworthy that Yakovlev and Lecours (1967) had postulated that myelin formation might continue to increase in the prefrontal cortex well into the 3rd or perhaps even 4th decade of life. Although empirical evidence for this hypothesis has been lacking, the recent findings described earlier make this idea seem quite plausible.

The Formation of Synaptic Connections

Like myelination, synapse formation is a relatively late aspect of the development of the central nervous system; the preponderance of these functional connections appear during the postnatal period. There are some axons that seem primed to form synaptic connection prenatally but do not do so. For example, during embryogenesis, afferent fibers from the thalamus grow toward the cortical mantle and eventually penetrate inward toward layer IV (Wise & Jones, 1978). In rodents, however, the ingrowth of thalamo-

Perforant Pathway and Distal Cingulum Bundle

Figure 5.5 Increased myelination in the parahippocampal gyrus of the human brain during the postnatal period. Comparing 11- and 17-year-old subjects, an increase of myelin staining is seen in the superior medullary lamina located along the surface of the subiculum and presubiculum at the later age (upper panel). This area contains fibers of the cingulum bundle and probably some from the basolateral amygdala. When this staining was quantitated in a large cohort of 163 psychiatrically and neurologically normal individuals, a substantial increase was observed during the 2nd decade (lower panel). Although the myelin seems to plateau through the 3rd and 4th decades, it again shows a significant (50%) increase during the 5th and 6th decades. (Upper courtesy of NIMH; lower from “Myelination of a Key Relay Zone in the Hippocampal Formation Occurs in the Human Brain during Childhood, Adolescence, and Adulthood,” by F. M. Benes, M. Turtle, Y. Khan, and P. Farol, 1994, *Archives of General Psychiatry*, 51, pp. 477–484.)

cortical fibers is not complete until the 3rd postnatal day, and commissural fibers begin to enter the homologous cortex in the contralateral hemisphere only by postnatal day 5 and attain a mature pattern of connectivity by postnatal day 7 (Wise & Jones, 1978). The afferent fibers seem to be present before a mature dendritic tree is in evidence, and

the formation of dendritic spines may be regulated by these afferent inputs (Wise, Fleshman, & Jones, 1979). For rats, the 1st postnatal week is considered to be similar to the prenatal period of primates and, consistent with this, commissural fibers arising from the principal sulcus of the monkey brain have been reported to penetrate into the homologous cortical region of the opposite hemisphere during the late embryonic period (Goldman-Rakic, 1981).

The density of synapses first increases toward peak levels at approximately 5 to 8 years of age in the human cortex, then decreases dramatically through early adolescence (Huttenlocher, 1994; Huttenlocher & Dabholkar, 1997). The latter process is called pruning and is believed to play a role in the acquisition of mature patterns of connectivity. Presumably, weakly active synapses are eliminated as functionally reinforced ones are maintained.

Dendritic Spine Morphogenesis

An important component to the maturation of dendritic structure is the formation of spines. These structures, primarily found on the dendritic arborizations of pyramidal neurons, are associated with the appearance of enhanced functional capabilities. In the hippocampus, the process of dendritic spine morphogenesis is associated with complex changes in a variety of protein constituents, such as F-actin fibrils, debrina, and the postsynaptic density protein PSD95 (Takahashi et al., 2003). Two different isoforms of debrin are expressed during embryogenesis (Debrin E) and adulthood (Debrin A) and appear to trigger the formation of F-actin fibrils into clusters. This process is associated with the appearance of filopodia-like protuberances along the dendrites of pyramidal cells. N-methyl-D-aspartate (NMDA) receptor activity regulates F-actin clustering in mature hippocampal neurons (Halpain, Hipolito, & Saffer, 1998), but it is not yet known whether a similar mechanism is at work during embryogenesis. PSD95 is associated with the appearance of mature spine morphology with a cap and a stalk, as well as AMPA receptor trafficking (El-Hussein, Schnell, Chetkovich, Nicoll, & Bredt, 2000). It is clear that spine formation is a complex process that involves the regulation of many different classes of protein. It is well known that spines display a marked degree of plasticity, not only during prenatal development, but also even much later during the adult period. Brain-derived neurotrophic factor (BDNF) is another protein that contributes to the maintenance of dendritic spine morphology in the cortex (Gorski,

Zeiler, Tamowski, & Jones, 2003). Based on these findings, it seems likely that the appearance and resorption of spines probably involves complex changes in the regulation of transcription, translation, and post-translational modification of proteins such as debrin and PSD95.

The Development of Afferent Inputs to the Cortex

During normal brain development, the entry of various types of afferent fibers to the cortex follows a carefully timed sequence. Two principal inputs to the cortex, one arising from the thalamus and one from the contralateral cortex, show such a sequential progression. During prenatal stages in rats, fibers from the thalamus extend toward the cortical mantle and either stop immediately beneath or begin to enter layer IV (Wise & Jones, 1978). In the rat somatosensory cortex, the ingrowth of thalamocortical fibers toward specific neuronal elements, particularly those in layer IV, continues after parturition and is not complete until approximately the 3rd postnatal day (Wise et al., 1979). In contrast, commissural inputs arising from the homologous cortex of the opposite hemisphere begin entering the somatosensory cortex at 5 days postnatally and attain a mature degree of connectivity by the end of the first postnatal week.

Developmental Changes in Specific Neurotransmitter Systems

The maturation of the prefrontal cortex must involve obligatory changes in both intrinsic and extrinsic neurotransmitter systems that mediate its activity. Although there is a dearth of specific information available regarding their development in human brain, the discussion that follows considers data obtained from studies in rodents where developmental changes of cortical neurotransmitters have been extensively characterized. Although it is true that the specific timing of developmental changes can vary considerably from one species to another, there are nevertheless some general principles that can be formulated from the studies of rodent and, to a lesser extent, primate brains. In this regard, it is useful to point out that the equivalent of adolescence in rats occurs between postnatal weeks 3 and 8, and the early adult period begins at approximately postnatal day 60. Where available, studies in the developing human brain are also described.

Intrinsic Neurotransmitters

The two most broadly understood neurotransmitters that are intrinsically present in virtually all local circuits and

provide excitatory and inhibitory synaptic responses are glutamate and GABA, respectively.

Glutamate. The amino acid glutamate and the closely related compound aspartate are generally considered to be the transmitters employed by pyramidal neurons projecting to both cortical and subcortical locations (Streit, 1984). The time course for the maturation of various glutamatergic pathways is probably different. For example, the corticocortical projections originating in the visual cortex of the rat brain attain adult levels of glutamate before their corticostriatal counterparts projecting to the caudate nucleus (Johnston, 1988). Interestingly, 2 days after birth, the levels of the glutamate reuptake mechanism is 30% of the levels that are eventually seen at P15. In the visual cortex and in the lateral geniculate nucleus, the reuptake mechanism attains adult levels by P15 and P20, respectively (Kvale, Fosse, & Fonnum, 1983). High-affinity glutamate receptors also continue to change postnatally. Between P10 and P15, glutamate receptor binding activity increases by 30% and is 10 times higher than it will eventually be during adulthood (Schliebs, Kullman, & Bigl, 1986). After P15, however, the activity declines substantially through P25 (Schliebs et al., 1986). In rats monocularly deprived of visual input, the overall binding of glutamate is reduced in the lateral geniculate nucleus but not the visual cortex, and these reductions are maintained into adulthood (Schliebs et al., 1986). In the hippocampus, glutamate receptor binding increases up to P23 (Baudry, Arst, Oliver, & Lynch, 1981), possibly reflecting the persistence of long-term potentiation as an important component to both learning and memory (Johnston, 1988).

Gamma-Aminobutyric Acid. GABA is thought to be the most important inhibitory neurotransmitter in mammalian brains, particularly in humans. Generally speaking, the activity of the GABA reuptake mechanism seems to increase before the activity of glutamate decarboxylase (GAD) shows appreciable increments (Coyle & Enna, 1976). At birth, the amount of GABA is half that seen in adults, but the adult amounts are not attained until the 2nd postnatal week. The number of GABA-immunoreactive (GABA-IR) neurons present in the medial prefrontal cortex of rat brains reaches a peak density at approximately P5, but thereafter decreases sharply between P10 and P20 as the surrounding neuropil expands (Vincent, Pabreza, et al., 1995). GABA terminals, however, increase in number between postnatal days 7 to 12 for the deeper layers of this region (Figure 5.6), but show an inside-out progression as they continue to increase in number in superficial laminae until the 3rd postna-

tal week (Vincent, Pabreza, et al., 1995). Although GAD levels are negligible at birth, they attain adult levels by the 3rd postnatal week (Johnston & Coyle, 1980).

The amount of GABA and benzodiazepine receptor activity does not begin to show appreciable increases until the 1st postnatal week, but thereafter shows a sharp rise during the 2nd week and an additional 15% increment between the 2nd and 7th postnatal weeks (Candy & Martin, 1979). In contrast, the reuptake mechanism for GABA peaks by the 2nd postnatal week, but later, in the 7th week, it decreases. In the human brain, GABA receptor binding activity shows a five-fold increase during the perinatal period (Brooksbank, Atkinson, & Balazs, 1981; Diebler, Farkas-Bargeton, & Wehrle, 1979) and an additional 100% increase for several weeks thereafter (Brooksbank et al., 1981). Functional inputs are thought to regulate the maturation of the GABA system. For example, in the cat visual cortex, dark-rearing from birth through the 6th postnatal week results in a decrease of normal GAD activity (Fosse, Heggelund, & Fonnum, 1989).

Extrinsic Neurotransmitters

Many different afferent systems project into regions of the neocortex and the hippocampal formation, but most are intrinsic to the cortex and are likely to use either glutamate or aspartate as a neurotransmitter. Afferent projections that are extrinsic to the cortex—those arising from noncortical locations—are of several different types; however, four have been particularly well investigated: (1) projections from the basal forebrain, pons, midbrain, and a diffuse region lying along the brain stem median raphe; (Lindvall, Bjorklund, & Divac, 1978) they use acetylcholine (basal nucleus; Mesulam, Mufson, Levey, & Wainer, 1984); (2) norepinephrine (locus coeruleus; P. Levitt & Moore, 1978); (3) serotonin (the raphe nuclei; Descarries, Beaudet, & Watkins, 1975); and (4) dopamine (ventral tegmental nuclei and substantia nigra; Berger, Tassin, Blanc, Moyne, & Thierry, 1974; Thierry, Blanc, Sobel, Stinus, & Glowinski, 1973). The developmental changes in each of these neurotransmitter systems are discussed separately.

Acetylcholine

Most of the acetylcholine (ACh) found in the cortex is derived from the basal forebrain (Johnston, McKinney, & Coyle, 1979), although a small amount may be synthesized by intrinsic cholinergic neurons (Bayer, 1985; Levey, Wainer, Raye, Mufson, & Mesulam, 1984). The neuronal cell bodies of the cholinergic system are generated early in gestation (Bayer, 1985), but they do not begin to accumulate appreciable amounts of choline acetyltransferase

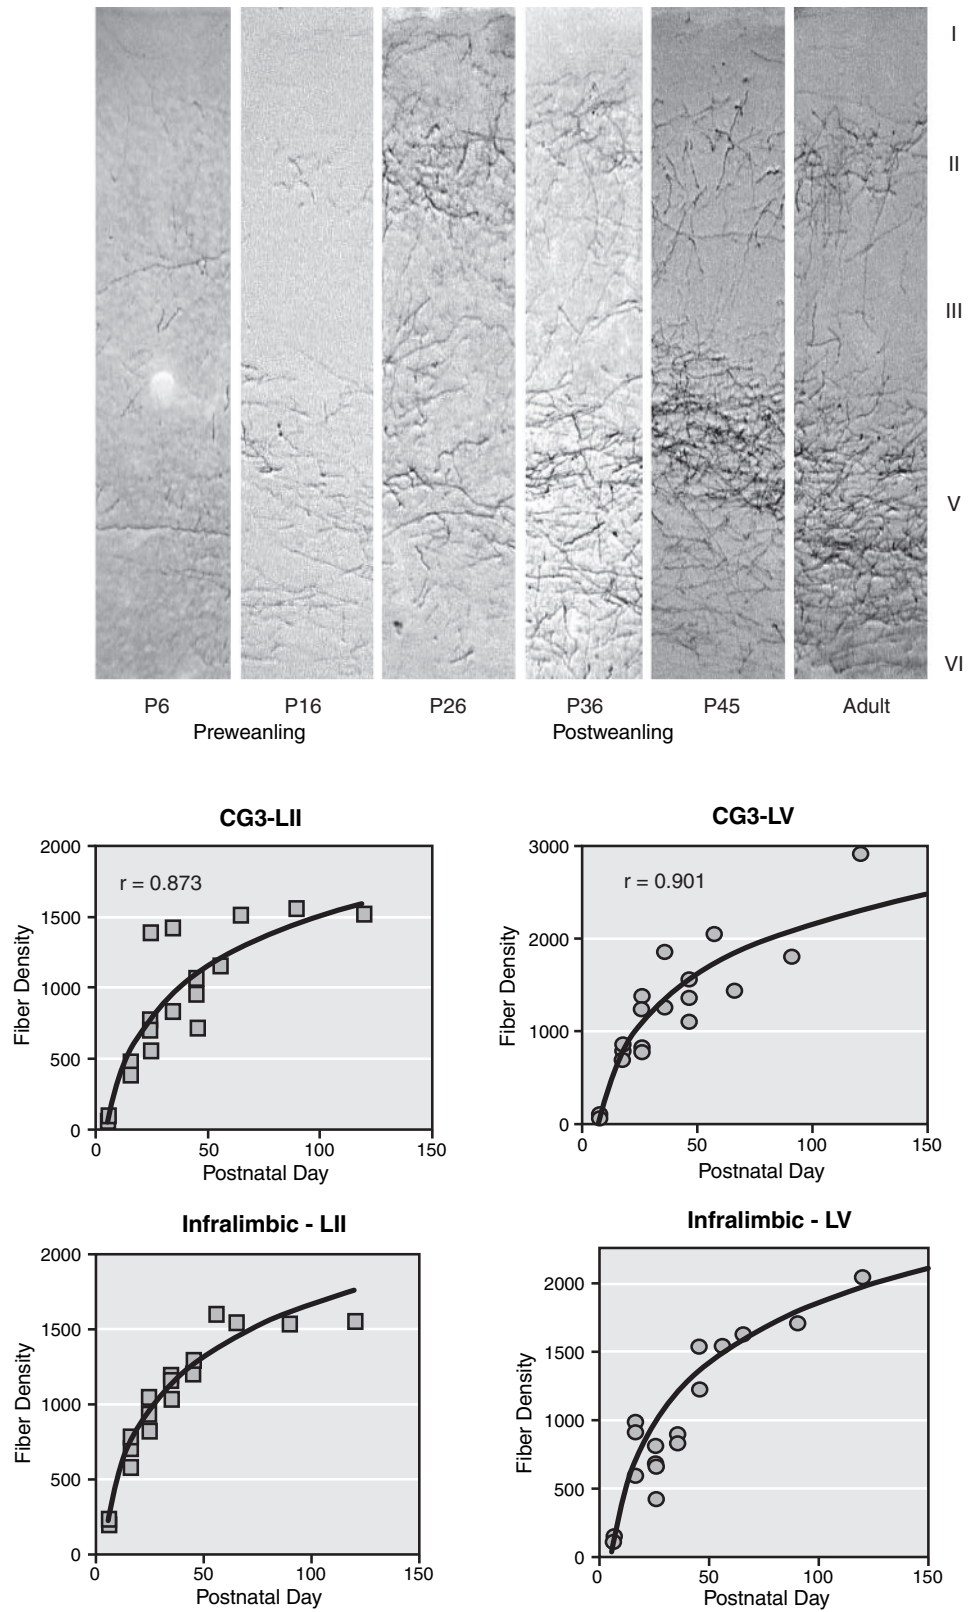

Figure 5.6 A photomontage showing an increase of fibers from the basolateral amygdala in the anterior cingulate cortex during the preweanling, postweanling, and adult periods (upper panel). Quantitative data for these fibers demonstrate a curvilinear increase between birth and the adult period (lower panel).

(ChAT) until after the 1st postnatal week, although this enzyme continues to increase at least until the 6th postnatal week (Johnston & Coyle, 1980). These changes in ChAT parallel the amount of binding activity at the receptor that mediates cholinergic effects in the cortex, the muscarinic *binding* site (Coyle & Yamamura, 1976), except that high-affinity sites for Ach are already fairly abundant at birth, and ChAT is not. The ingrowth of cholinergic fibers into the cortex occurs first in deeper layers and later in the superficial layers, a pattern that mirrors the inside-out progression seen for cortical ontogeny. In humans, cholinergic fibers have been observed to enter the cortex as early as 12 to 22 weeks of gestation (Candy et al., 1985); however, by birth, the overall levels of ChAT remain low, and adult levels are not attained until approximately age 10 (Diebler et al., 1979). In sharp contrast to rodents, muscarinic receptor activity in the human cortex is highest at birth and progressively diminishes during the 2nd through 6th decades (and possibly longer), perhaps as a result of synaptic pruning (Ravikumar & Sastary, 1985). In the human cortex, acetylcholinesterase, the enzyme that degrades Ach, is found principally in interneurons during the 1st postnatal week, but later shows a progressive increase in pyramidal cell bodies of layer III, where it reaches peak levels in young adults (Kostovic, Skavic, & Strinovic, 1988). Because upper cortical layers are predominantly involved in associative connections, these latter changes could reflect maturational changes in cognitive activity.

Norepinephrine

Noradrenergic cell bodies of the locus coeruleus undergo their last mitotic division in rat brains at gestational days 12 to 14 (Lauder & Bloom, 1974) and in monkeys at gestational days 27 to 36 (P. Levitt & Rakic, 1982). By birth, there is a rather extensive network of noradrenergic fibers in the cortex, and their density is considerably greater than that seen in adults (Coyle & Molliver, 1977). In rats, tyrosine hydroxylase (TH), the enzyme involved in the synthesis of norepinephrine and dopamine, increases steadily between the 1st and 7th postnatal weeks (Johnston & Coyle, 1980). The beta-adrenergic receptor increases sharply between the 1st and 2nd postnatal weeks, before plateauing (Harden, Wolfe, Sporn, Poulos, & Molinoff, 1977). Studies of the cat have suggested that norepinephrine may play a key role in the plasticity of synaptic connections (Kasamatsu & Pettigrew, 1976). Following monocular visualized nonvaricose fibers with a vertical orientation, it is unlikely that these fibers originated from these latter subcortical nuclei.

Serotonin

The timing of developmental changes in the serotonin (5-hydroxytryptamine or 5-HT) system is similar to that observed for the noradrenergic system (Hamon & Bourgoignie, 1977; Hedner & Lundberg, 1980). Serotonin-containing neurons of the raphe nuclei in rat brains (Descarries et al., 1975) are first visualized between gestational days 13 and 17, when some of their axons have already grown toward the pyriform cortex (Wallace & Lauder, 1983). As seen with other transmitter systems in rat brains (see "Dopamine Systems"), 5-HT levels increase steadily between birth and the 4th postnatal week (Johnston, 1988). The synthesizing enzyme for 5-HT, tryptophan hydroxylase, is at 10% of adult levels by birth, but rises to adult levels by postnatal day 30 (Deguchi & Barchas, 1972). During the perinatal period, high-affinity 5-HT receptor binding activity, on the other hand, is approximately 33% of that seen in adults but does not attain adult levels until the 6th postnatal week (Uphouse & Bondy, 1981). In primates, 5-HT afferent fibers to the cortex appear to have established an adult pattern by postnatal week 6, and the levels of 5-HT continue to increase for an additional 2 to 3 weeks (Goldman-Rakic & Brown, 1982). In human brains, however, the density of 5-HT₂ binding sites shows a linear decline between 17 and 100 years of age; in the hippocampus, a similar but less striking change in this receptor also occurs (Marcusson, Morgan, Winblad, & Finch, 1984).

It has been suggested that timing for the ingrowth of serotonergic fibers may vary according to the degree of maturity for intrinsic circuits within a given region (Lidov & Molliver, 1982). Interestingly, at birth, the serotonin projection to the sensory cortex is found preferentially within layers IV and VI, the two laminae predominantly involved in receiving thalamic afferents. Because the arrival of serotonin fibers precedes that of the thalamocortical afferents, it has been suggested that the serotonergic innervation to the cortex may provide a trophic influence on thalamic fibers and/or their target neurons (Wise & Jones, 1978).

Dopamine

Dopamine cells in the ventral tegmental area and substantia nigra of rat brains (Berger et al., 1974; Thierry et al., 1973) begin to differentiate on embryonic day 11 and continue this process through day 15 (Lauder & Bloom, 1974). Afferent dopamine fibers first arrive near the frontal cortex as early as E16 (Verney, Berger, Adrien, Vigny, & Gay, 1982); however, by birth, these axons begin to penetrate into the cortical mantle and establish an abundant innervation by postnatal week 2 for the frontal area and postnatal

week 3 for the cingulate region (Berger & Verney, 1984). Dopamine afferents to the prefrontal region also follow the typical inside-out progression seen for cholinergic inputs, entering the infragranular layers first and the supragranular layers last (Kalsbeek, Voorn, Buijs, Pool, & Uylings, 1988). As shown in Figure 5.7, a full complement of dopamine fibers in the anterior cingulate cortex is not established until adulthood (Benes, Vincent, Molloy, & Khan, 1996; Kalsbeek et al., 1988; Verney et al., 1982). Dopamine concentrations also rise steadily until adulthood (Johnston, 1988). Dopamine receptors, on the other hand, are expressed in the cortex before birth and continue to increase toward adult levels through postnatal day 31 of rats (Bruinink, Lichtensteiner, & Schlumpf, 1983; Deskin, Seidler, Whitmore, & Slotkin, 1981).

Developmental Similarities among Transmitter Systems

Based on the previous discussion, there are several developmental characteristics that are similar across neurotransmitter systems, and there is no reason to believe that the situation is different for the prefrontal cortex. For example, the progenitor cells responsible for the elaboration of both intrinsic and extrinsic transmitter systems in the cortex become postmitotic long before they show appreciable differentiation of their respective neurotransmitter phenotypes. In addition, virtually all neurotransmitter systems are present in the cortex at birth but require further maturation. Finally, the postnatal development of most transmitter systems continues beyond the weanling period (similar to early adolescence in humans), during which important changes in gonadal maturity are occurring and overlap with the postweanling period (similar to late adolescence, when changes in emotional maturity are occurring). Although there is a dearth of information in this area regarding the human brain, available evidence suggests that postnatal maturation of both the cholinergic and serotonergic systems may continue throughout childhood and adolescence and, in some cases, may persist throughout the life span of the normal individual. Based on observations in rats, however, it seems likely that changes in the dopamine system are also occurring until the early adult period.

Developmental Interactions between Intrinsic and Extrinsic Cortical Projection Systems

It is evident from the previous discussion that the postnatal maturation of both intrinsic and extrinsic neurotransmitter systems is extensive. At this juncture, a reasonable question

to ask is whether these progressive postnatal changes may involve an increase in the degree to which some or all of these transmitter systems are interacting with one another.

Dopamine-GABA Interactions

A recent study has suggested that frequent appositions occur between dopaminergic afferents and both pyramidal neurons and GABAergic interneurons in the medial prefrontal cortex of adult rats (Benes, Vincent, & Molloy, 1993). As shown in Figure 5.7, the frequency of these contacts was compared for preweanling and postweanling rats, and it was found that there is a threefold increase in the number of dopamine-immunoreactive varicosities found in contact with pyramidal cells, but a fivefold increase in the number on nonpyramidal neurons in layer VI of the rat medial prefrontal cortex. In layer II of this region, there was a sevenfold increase on nonpyramidal neurons, but no change on pyramidal cells. These findings suggest that (1) postnatal increases in the interaction of one transmitter system with another probably do occur to a significant degree, (2) such changes may vary in magnitude according to cortical layer, and (3) changes of this type may occur differentially for one neuronal cell type versus another within a given cortical layer. In other words, postnatal maturational changes in the cortical neurotransmitter system may be far more complex than was heretofore suspected, and to fully understand the implications of postnatal ontogeny, a clear delineation of how changes in neurochemical markers may be reflected in alterations of specific synaptic connectivity is needed.

A variety of studies have demonstrated that both pyramidal and nonpyramidal neurons express receptors that mediate the effect of dopamine. For example, dopamine D1 receptor binding activity has been localized to nonpyramidal cells (Vincent, Khan, & Benes, 1993), but in another study it was associated with pyramidal cells (Bergson et al., 1995) in the prefrontal cortex. This apparent discrepancy can be explained by methodologic and species differences in these two studies, because messenger RNA for both the D1 and D2 subtypes has been localized in both pyramidal and nonpyramidal neurons (Huntley, Morrison, Prikhozhan, & Sealfon, 1992). Consistent with this, a large proportion of interneurons in rat medial prefrontal cortex (mPFCx) have been found to express D1 and D2 binding activities (Vincent, Khan, & Benes, 1995), and studies in which *in vitro* microdialysis was employed have demonstrated that agonists for both the D1 and D2 subtypes are associated with a reduction in the release of 3H-GABA (Penit-Soria, Audinat, & Crepel, 1987; Retaux, Besson, & Penit-Soria, 1991a, 1991b). Thus, as suggested by these re-

Figure 5.7 Ingrowth of dopamine fibers in the anterior cingulate cortex at different postnatal ages (upper panel). These darkfield photomicrographs show a progressive increase in the density of dopamine fibers between the preweanling (P11) period and early adulthood. Using a double localization technique, dopamine fibers also show a progressive increase in the number of contacts they form with GABAergic interneurons. *Source:* From “Increased Interaction of Dopamine-Immunoreactive Varicosities with Gaba Neurons of Rat Medial Prefrontal Cortex Occurs during the Postweanling Period,” by F. M. Benes, S. L. Vincent, R. Molloy, and Y. Khan, 1996, *Synapse*, 23(4), pp. 237–245. Reprinted with permission of Wiley-Liss a subsidiary of John Wiley & Sons, Inc.

sults, cortical dopamine projections can potentially exert a significant nonsynaptic modulatory influence on GABAergic cells in rat mPFCx.

Using a specific marker for GABAergic neurons, it has been possible to demonstrate that dopamine fibers show a progressive increase in the frequency with which they form appositions with inhibitory interneurons (Benes et al., 1996). Between the preweanling and postweanling periods, there was a 55% increase in the frequency of these interactions, and between the postweanling and early adult period

(P60) there was an additional 85% increase (see Figure 5.7). Overall, during the postnatal period, there was a 150% increase in the interaction of dopamine fibers with GABA-immunoreactive neuron somata in the medial prefrontal cortex of rat brains.

Convergence of Dopamine and Serotonin Fibers on Prefrontal Neurons

Serotonin fibers are believed to converge on the same pyramidal cells and GABA neurons that receive inputs from

catecholaminergic neurons (Gellman & Aghajanian, 1993). A triple immunofluorescence study was able to confirm that this arrangement occurs in the medial prefrontal cortex of rats to an extensive degree (Taylor & Benes, 1996). It is noteworthy that pyramidal neurons also received inputs to their somata from both TH- and 5-HT-IR fibers. Because these latter cell bodies also received axosomatic inputs from GAD-IR terminals, it was concluded that the principal projection cells of this regions receive a “trivergence” of inputs from the GABA, dopamine, and serotonin systems (Benes, Taylor, & Cunningham, 2000). With regard to the serotonin system, the 5-HT₂ receptor protein has been immunocytochemically localized to presumptive GABAergic interneurons in layer II of the pyriform cortex (Morilak, Garlow, & Ciaranello, 1993).

It is well-established that GABA is an inhibitory neurotransmitter that plays a pivotal role in cortical integration (E. G. Jones, 1987). There are many different subtypes of GABAergic interneurons in the cortex, but the most basic dichotomy is between basket cells that exert inhibitory effects on pyramidal neurons (E. G. Jones & Hendry, 1984) and double bouquet cells that are disinhibitory in nature (Somogyi & Cowey, 1984); the latter act by inhibiting other GABAergic cells. GABAergic interneurons play a very critical role in discriminative aspects of cortical processing, such as orientation selectivity (Sillito, 1984).

Functional Implications of Monoaminergic Convergence

Physiological studies have demonstrated that SKF38393, a D₁ agonist, and RU24926, a D₂ agonist, have both been found to inhibit the electrically evoked release of 3H-GABA in rat mPFC (Penit-Soria, Retaux, & Maurin, 1989; Retaux et al., 1991a, 1991b), although D₂ agonists have paradoxically been found to increase the spontaneous release of GABA. This apparent paradox could potentially be explained by an initial depolarization leading to either a presynaptic inhibition or a refractor period in GABA cells. Because the D₂ receptor is mainly associated with inhibitory mechanisms, the complexity of interactions between dopamine terminals and GABA cells in the prefrontal cortex might well mask a similar effect on evoked GABA release. Specifically, dopamine binding to D₂ receptors on some terminals could produce an inhibition of a GABA neuron (Retaux et al., 1991b). It is plausible that dopamine fibers interact with both inhibitory and disinhibitory GABAergic elements, and this could help to explain the paradoxical effects of D₂ agonists on spontaneous versus evoked release of dopamine in the prefrontal cortex. For the serotonin system, the results of an intracellular

recording study have indicated that the effect of this monoamine on GABA cells is blocked by 5-HT₂ antagonists (Sheldon & Aghajanian, 1990). Overall, serotonin appears to induce hyperpolarizing postsynaptic potentials in pyramidal neurons, and these are believed to be mediated via the effect of this transmitter on GABAergic interneurons (Sheldon & Aghajanian, 1991).

Although it is clear that both dopamine and serotonin can directly influence the activity of cortical interneurons, there is very little currently known regarding any direct interactions between these two systems on individual GABAergic cells. Some investigators believe that serotonin can increase the release of dopamine in the nucleus accumbens (Broderick & Phelix, 1997), corpus striatum (Broderick & Phelix, 1997; Gudelsky & Nash, 1996; West & Galloway, 1996), and prefrontal cortex (Gudelsky & Nash, 1996). Contrariwise, others have suggested that serotonin may actually decrease the release of dopamine, because exposure to selective serotonin receptor antagonists has been associated with an increase of extracellular dopamine concentration (Howell, Czoty, & Burd, 1997; Pehek, 1996). None of these studies has attempted to assess such an interaction at the level of individual neurons. It is important to point out that functional interactions between these two monoaminergic systems may not be mediated solely at the cortical level, but could be mediated, at least in part, at midbrain levels, where the ventral tegmental area and nucleus raphe dorsalis are both located.

Postnatal Plasticity and Convergence of Dopamine-Serotonin Interactions

As noted, the serotonin systems has been found to influence the plasticity of the developing neocortex, as it exerts a trophic influence on the ingrowth of thalamocortical fibers (D'Amato et al., 1987). With respect to the current discussion, it is pertinent to ask whether serotonin might also exert a neuroplastic influence on the late ingrowth of dopamine fibers into the medial prefrontal cortex during early adulthood. To explore this issue, a series of experiments were conducted using 5,7-dihydroxytryptamine, a specific toxin to serotonergic neurons, to lesion the dorsal raphe nucleus of rat brains during the neonatal period (Taylor, Cunningham, & Benes, 1998). The distribution of TH-IR varicosities was assessed in the ventral tegmental area (VTA), where dopaminergic afferents to the cortex originate, and in the medial prefrontal area. The lesioned rats showed a marked reduction in the visualization of 5-HT-IR somata in the ventral periaqueductal gray, but the VTA showed no reduction in staining. In the medial prefrontal

area, 5-HT fibers were also markedly reduced, whereas TH-IR fibers were abundantly present throughout the cortical mantle. When the numerical density of TH-IR varicosities was determined, a significant increase was noted, particularly in layer V, where the 5-HT innervation of the cortex is quite dense. These results suggest that there may be a competition between dopamine and 5-HT fiber systems within the prefrontal cortex of rat brains.

To test this hypothesis further, a second series of experiments was performed in which the dopamine projections to medial prefrontal cortex (mPFC) were lesioned using 6-OH-DOPA administration at P6. As before, the animals were allowed to mature and were sacrificed at P60. Although it was postulated that there would be a sprouting of the serotonergic fibers, a quantitative analysis revealed that the numerical density of these latter fibers was actually reduced (Cunningham, Connor, Zhang, & Benes, 2005). This finding suggests that the interaction between dopaminergic and serotonergic fibers in the cortex are much more complex than was previously believed. This paradoxical finding may be explained, at least in part, by interactions of these two monoaminergic systems at brain stem levels.

The Postnatal Ingrowth of Basolateral Amygdalar Fibers into the Cingulate Cortex

The anterior cingulate cortex (ACCx) plays a central role in the mediation of emotional, attentional, motivational, social, and cognitive behaviors (Vogt, Finch, & Olson, 1992). The amygdala, specifically its basolateral subdivision (BLA), sends a massive input to cortical layers II and V of mPFC (Amaral, Price, Pitkanen, & Carmichael, 1992; Van Hoesen et al., 1993; Vogt, Vogt, Nimchinsky, & Hof, 1997) and contributes to the recall of emotional information (McGaugh, Ferry, Vazcarjanova, & Roosendaal, 2000), aversive conditioning (Fanselow & LeDoux, 1999), decision making (Bechara, Damasio, Damasio, & Lee, 1999), and goal-directed behavior (Schoenbaum, Chiba, & Gallagher, 2000). Because these latter behaviors are all showing maturational changes during childhood and adolescence, normal postnatal changes in the distribution and synaptic connectivity of the amygdala with the anterior cingulate cortex have been characterized. Given the established role of the amygdala (LeDoux, 2000a, 2000b) and anterior cingulate cortex (Devinsky, Morrell, & Vogt, 1995) in the mediation of emotional behavior, this connectivity could play a central role in modulating the emotional component of emotionally related learning responses, particularly under conditions of stress (Gray & Bingaman, 1996).

As shown in Figure 5.6, amygdalofugal fibers become organized into a bilaminar distribution occupying cortical layers II and V by postnatal day 16 (Cunningham, Bhattacharyya, & Benes, 2002). By adulthood, this bilaminar distribution is present through the rostrocaudal extent of the anterior cingulate region, as the fiber density within these layers becomes progressively more dense. Figure 5.6 illustrates the progressive increase of basolateral amygdalar fibers between birth and the start of the adult period at postnatal day 60. During the neonatal period, there was a paucity of fibers, and those present lacked a clear laminar organization. Within 2 weeks, however, although still sparse, fibers began to organize into the characteristic bilaminar distribution seen in the adult. Subsequently, there was a striking increase in fiber density across the various postweaning time points, and this progression continued into adulthood. For each developmental time point, the density of amygdalocortical fibers shows increases in both layers II and V.

Labeled amygdalar fibers forming synapses can also be identified using an electron microscope. Contacts between labeled axons and cortical structures could be found as early as the equivalent of early adolescence (P25 in rats), but these interactions became more numerous at later time points equivalent to adulthood (P60 and P120). The most striking change was a pronounced increase of axospinous synapses that are believed to be excitatory in nature. These findings are consistent with those of Bacon, Headlam, Gabbott, & Smith (1996), which showed that dendritic spines are the principal postsynaptic target for amygdalofugal fibers in the adult.

Overall, it appears that the anterior cingulate cortex receives a progressive and dramatic ingrowth of fibers originating from the posterior aspect of the basolateral nucleus and the formation of functional synapses. Such changes are theoretically capable of providing enhanced feed-forward excitation to the anterior cingulate cortex during the equivalent of adolescence and early adulthood. Electrophysiological studies have demonstrated that stimulation of the BLA results in a preponderance of inhibitory postsynaptic potentials within the rat mPFC (Perez-Jaranay & Vives, 1991). Because amygdalocortical projection neurons are glutamatergic (McDonald et al., 1989), and are therefore likely to be excitatory in nature, the predominant target of amygdalofugal projections to the mPFC may be GABA interneurons. Presumably, stimulation of these inhibitory cells by BLA fibers results in inhibitory postsynaptic potentials in projection neurons. Indeed, amygdalofugal fibers appear to make frequent contacts with GABAergic cell bodies and processes (Benes, Bhattacharyya, & Cunningham, 2002).

These results complement a variety of other studies demonstrating late postnatal developmental changes. In addition to an estimated loss of 50% of neocortical synapses (Huttenlocher & Dabholkar, 1997), myelination continues until the 6th decade in humans (Benes, 1989; Benes et al., 1994). The amygdala itself also undergoes developmental changes during adolescence, showing increased vulnerability to kindled seizures (Terasawa & Timiras, 1968) and decreased c-Fos expression under stressful conditions (Kellogg, Awatramani, & Piekut, 1998). The postnatal increase in density of amygdalocortical fibers and their synapses described earlier parallels the emotional maturation that is associated with early and late adolescence.

As discussed in the beginning of this chapter, current theories suggest that constitutional differences in temperament may involve the amygdala and its interconnectivity with ACCx (Kagan & Snidman, 1991b). The amygdala also mediates more primitive behaviors, such as aggression, fear, and sexual activity (Armony, Servan Schreiber, Cohen, & LeDoux, 1995; Davis, 1992), all of which influence socialization. For example, cats with abnormally increased neuronal activity within the BLA show a reduced ability to interact socially and tend to hide when introduced to novel stimuli (Adamec, 1978, 1991), and animals with amygdala ablations appear to lose the fear response (Kluver & Bucy, 1937). In humans, lesions of the amygdala result in a decrease or absence of conditioned fear responses to aversive stimuli, and it is believed that the amygdala provides the affective coloration to emotionally charged stimuli (Bechara et al., 1999). Furthermore, the emotional valence provided by the amygdala is critical for appropriate processing of multimodal sensory information by the mPFC (Bechara et al., 1999; LeDoux, 1993). Patients with damage to the cingulate cortex or with therapeutic cingulotomies show a decreased ability to experience and express affect (Damasio & Van Hoesen, 1983), increased docility, and indifference (Laplane et al., 1981).

It seems evident, therefore, that cognitive and emotional development are related to amygdalocingulate connectivity. Because projections from the amygdala to ACCx have been implicated in social functioning (MacLean, 1985), the continued development of this system during adolescence may enable an individual to modulate anxiety and fear and become more socially adept. Thus, normal emotional maturation during the teenage period may involve ontogenetic changes in amygdalocingulate connectivity like those demonstrated in the present study (Cunningham et al., 2002). Contrariwise, abnormal emotional maturation could hypothetically be related to aberrant sprouting of this connectivity within the cingulate cortex during the adolescent period. Because psychosis, depression, substance

abuse, violence, and suicidality all typically present during adolescence, a comprehensive understanding of postnatal changes in amygdalocingulate connections will provide a unique opportunity for increasing our understanding of both normal and abnormal behaviors that manifest during this critical stage of emotional development (Cunningham et al., 2002). By examining the boundaries between abnormal and normal development during adolescence, it may be possible to articulate more clearly the diversity in the course of development that may occur during this period (Cicchetti & Rogosch, 2002).

This discussion illustrates that it is likely that the ontogenesis of the limbic lobe spans not only the embryonic period, but also an extensive postnatal interval that includes the early adult period and possibly even beyond. During embryogenesis, the developmental processes that are operative encompass a broad range of phenomena that include the proliferation, migration, and differentiation of neurons, not only those intrinsic to the prefrontal cortex, but also ones extrinsically derived from a variety of subcortical regions that send significant projections to it. These latter fiber systems include projections from the thalamus, as well as those that originate in the dorsal raphe nucleus, ventral tegmental area, and locus coeruleus. Unlike the specific afferent systems from the thalamus, the monoaminergic systems may continue their growth and maturation for a much longer period of time that extends into adulthood. As such, these latter systems may play an important role in modulating the activity of intrinsic circuits within the prefrontal cortex and may ultimately contribute to the acquisition of mature patterns of cognitive behavior that are mediated by this region (Goldman-Rakic, 1998; Goldman-Rakic & Brown, 1982). Although their developmental time frame is different, the dopaminergic and serotonin systems converge on intrinsic prefrontal neurons and influence the nature of their activity (Lambe, Krimer, & Goldman-Rakic, 2000). This implies that these two monoaminergic systems may be particularly important to our understanding of how neuronal plasticity contributes to the sculpting of neural circuitry within the adult prefrontal cortex.

THE ROLE OF THE AMYGDALA IN THE PATHOPHYSIOLOGY OF MENTAL DISORDERS

The hypothesis that the basolateral amygdala may play a role in the pathophysiology of Schizophrenia has been suggested, in part, by the fact that this region sends a massive projection to layer II of the anterior cingulate cortex, where several microscopic anomalies have been observed in Schizophrenia (Benes & Bird, 1987; Benes et al., 1987; Benes, McSparren, Bird, SanGiovanni, & Vincent, 1991;

Benes, Sorensen, et al., 1992; Benes, Todtenkopf, & Taylor, 1997; Benes, Vincent, Alsterberg, Bird, & SanGiovanni, 1992; Woo, Walsh, & Benes, 2004). More direct evidence, however, comes from the report of a decrease of high-affinity GABA uptake in the amygdala of the post-mortem schizophrenic brain (Reynolds, Czudek, & Andrews, 1990). It is relevant, therefore, to consider more closely the specific ways in which this region interacts with the hippocampal formation, particularly as both of these regions have been found to show volume reduction in brain imaging studies of Schizophrenia (for a detailed review, see Lawrie & Abukmeil, 1998).

The basolateral subdivision of the amygdala comprises a frontotemporal system that innervates several key components of the corticolimbic system, including the hippocampus formation (Swanson & Petrovich, 1998). The projections of the amygdala to the hippocampus are rather complex and include the perforant pathway terminations in the stratum moleculare of the area dentata, as well as various other fiber systems that enter the CA subfields either through the stratum oriens (i.e., to CA3) or the stratum moleculare (Pikkarainen, Ronkko, Savander, Insausti, & Pitkanen, 1999). The direct projections of the basolateral complex to the CA subfields, together with its indirect influences exerted via the entorhinal region, constitute a compelling network to consider in relation to Schizophrenia. Interestingly, blockade of the GABA_A receptor results in marked changes in the regulation of emotional responses mediated by this region (Davis, Rainnie, & Cassell, 1994; Sanders & Shekhar, 1995). Because a dysfunction of the GABA system is believed to occur in the amygdala in Schizophrenia, an increased outflow of activity from this latter region to the entorhinal region and hippocampus could contribute to the disturbances in affective experience and the heightened response to stress that are observed in this disorder.

An increase of incoming amygdalar activity to the cingulate region would likely produce important shifts in the relationship of this area with the various regions to which it, in turn, projects. Recent investigations of the anterior cingulate cortex in schizophrenic patients have also suggested a model (Figure 5.8) in which there may be a loss of GABAergic neurons, particularly in layer II (Benes, McSparren, Bird, Vincent, & SanGiovanni, 1991; Benes, Vincent, et al., 1992). In this setting, excessive excitatory activity emanating from increased associative inputs could theoretically be exacerbated by diminished inhibitory activity from GABAergic basket neurons (Benes, Sorensen, et al., 1992). It has been suggested that the effects of increased excitatory inputs and decreased inhibitory activity (Benes, Sorensen, et al., 1992) could contribute to the over-inclusive thinking and loss of a “central filtering” mecha-

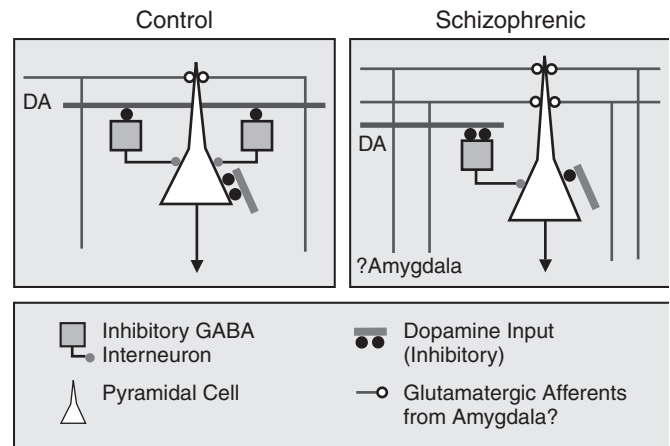

Figure 5.8 A schematic depiction of an intrinsic circuit in the anterior cingulate cortex of normal and schizophrenic individuals. In the normal circuit (left), a pyramidal neuron receives GABAergic inputs from two inhibitory interneurons. Each GABA cell receives one dopaminergic input which is inhibitory in nature. Two separate glutamatergic vertical fibers ascend to layer I, where they travel horizontally before forming excitatory connections with the distal portions of the pyramidal cell apical dendrite. In the schizophrenic circuit (right), there is only one GABAergic cell, depicting a loss and/or dysfunction of these cells. The remaining GABA cell receives an excess number of dopamine inputs, a change that has been referred to as a “mis-wiring.” At the same time, there are four glutamatergic vertical fibers coursing toward layer I and forming excitatory connections with pyramidal cell dendrites. In the schizophrenic circuit, less inhibitory activity would be available to modulate the excessive excitatory activity arising from the vertical associative inputs. From “Amygdalo-Cortical Sprouting Continues into Early Adulthood: Implications for the Development of Normal and Abnormal Function during Adolescence,” by M. G. Cunningham, S. Bhattacharyya, and F. M. Benes, 2002, *The Journal of Comparative Neurology*, 453, pp. 116–130. Reprinted with permission of Wiley-Liss a subsidiary of John Wiley & Sons, Inc.

nism, respectively, that have been described in this disorder (Detre & Jarecki, 1971). In addition, superabundant glutamatergic inputs could themselves be responsible for GABA neuron loss as a result of an excitotoxic injury (Rothman & Olney, 1986). Such an effect on inhibitory interneurons has been experimentally induced in adult rats using the excitotoxin kainic acid (Zhang et al., 1990). Because excitotoxic mechanisms have been associated with ischemic injuries to the brain (Rothman & Olney, 1986), it is possible that perinatal complication, such as prolonged labor (Jacobsen & Kinney, 1980), could result in a lower oxygen tension or high levels of glucocorticoids. Hypoxia does not appear to be a likely source of early neuronal damage in schizophrenic subjects because many different complications have been found in their obstetrical records, but most are not associated with a low oxygen tension. Rather, a nonspecific stress response, with unusually high circulating titers of

glucocorticoid hormone, would be a more likely setting in which damage to the immature brain might occur (Sapolsky, 1992; Sapolsky & Meaney, 1986). Reductions in neuronal cell content (Cotterrell, Balazs, & Johnson, 1972) have been associated with high levels of corticosterone early in life, making it plausible that a variety of stressors could induce alterations of brain circuitry by triggering a nonspecific stress response. It is noteworthy that glucocorticoids seem to potentiate the excitotoxic effects of kainic acid (Stein-Behrens et al., 1992), and such a mechanism could influence the proposed role of glutamatergic afferents in the pathophysiologic changes that occur in the anterior cingulate cortex and hippocampus of schizophrenic subjects. Because the cortex develops in an inside-out fashion (Sidman & Rakic, 1973) and basket cells of layer II are particularly immature in the human brain at the time of birth (Marin-Padilla, 1970b), it is possible that GABAergic interneurons may be particularly vulnerable to the effects of perinatal complications (Benes, 1993a). In this regard, it is worth noting that, in immature rat brains, neurons with NMDA receptors may have periods in which they exhibit hypervulnerability to even moderate amounts of receptor stimulation (Ikonomidou, Mosinger, Shahid Sallett, Labruyere, & Olney, 1989). Apparently, different populations of neurons show their own periods of peak vulnerability (Olney, Sesma, & Wozniak, 1993). Because GABAergic neurons of the corpus striatum are particularly sensitive to excitotoxic degeneration in adult rats (Schwarcz & Coyle, 1977), it is possible that basket cells in various layers of the immature cortex also show selective hypersensitivity to stimulation of NMDA receptors at particular stages of development. Indeed, excessive numbers of glutamatergic inputs to superficial laminae might be a predisposing factor for a perinatal hypoxic insult to result in a failure of cortical basket neurons to mature.

Although current hypotheses regarding the etiology of Schizophrenia favor a model in which an early brain injury plays a key role in this disorder (P. B. Jones, Rantakallio, Hartikainen, Isohanni, & Sipila, 1998; Seidman et al., 2000), it is also possible that an excitotoxic injury might occur later in the life of a schizophrenic individual (Benes, 2000; Benes, Sorensen, et al., 1992). This disorder has a characteristic onset between 16 and 25 years of age (Kraepelin, 1919), a period during which the human brain shows active myelination of a key corticolimbic relay area (Benes, 1989). Because the occurrence of myelination would be associated with an increased velocity of conduction (Huxley & Stampel, 1949), this developmental change might be expected to enhance associative processing in corticolimbic areas also found to have structural alterations in schizophrenics. In the setting of excessive associative inputs to the anterior cingulate cortex, an

increased release of glutamate occurring in response to emotional stress mediated through the BLA could theoretically trigger an excitotoxic response in the anterior cingulate cortex during the 2nd or 3rd decade of life.

FUTURE DIRECTIONS

There are several directions that developmental neurobiologic studies of Schizophrenia and affective disorders can follow in the coming years. These directions are discussed here in detail.

Identification of How Circuitry Is Altered

The most essential phase of developmental neurobiologic studies of Schizophrenia and other psychiatric disorders is the precise identification of abnormalities in the intrinsic circuits of involved brain regions. Each psychiatric disorder will require appropriate neurobiologic strategies.

Schizophrenia

As shown in Figure 5.9, the vertical axons depicted in the model shown in Figure 5.8 could potentially be fibers em-

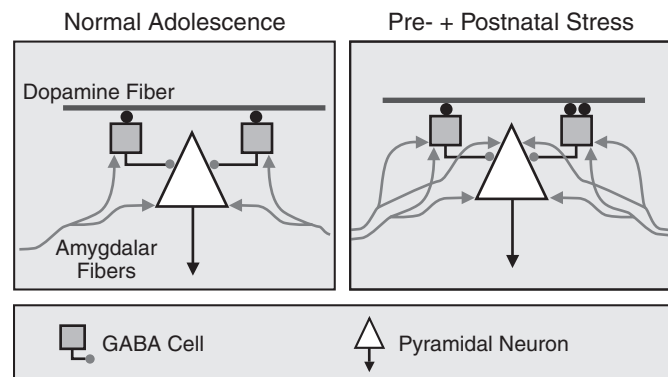

Figure 5.9 A schematic diagram similar to the one shown in Figure 5.8 showing a cortical pyramidal cell in the cingulate cortex that receives convergent inputs from dopaminergic and amygdalar fibers. Individuals exposed to both pre- and postnatal stress show an increased number of inputs from these two fiber systems. Under stressful conditions, some fibers release excess amounts of dopamine, and others release excess glutamate. At a critical stage of development, such as adolescence, these fiber systems are growing into the anterior cingulate cortex and may cause the intrinsic circuitry to decompensate in individuals exposed to severe stress during both the pre- and postnatal periods. From "Amygdalo-Cortical Sprouting Continues into Early Adulthood: Implications for the Development of Normal and Abnormal Function during Adolescence" by M. G. Cunningham, S. Bhattacharyya, and F. M. Benes, 2002, *The Journal of Comparative Neurology*, 453, p. 124. Reprinted with permission of Wiley-Liss a subsidiary of John Wiley & Sons, Inc.

anating from the basolateral amygdala. In individuals exposed to both pre- and postnatal stress, it is hypothetically possible that this fiber system could be induced to sprout as a result of heightened activity in the basolateral nucleus of the amygdala (BLN). In this setting, a hyperinnervation of both the dopamine and amygdalar projections converging on GABAergic cells could occur and mitigate oxidative stress and potentially apoptotic cell death. If dopaminergic projections are inhibitory in nature, would their activity tend to cancel that excitatory drive coming from the amygdala? It is important to emphasize that these two fiber systems are fundamentally different in terms of their mechanisms of action. Whereas amygdala afferents to the cortex engage in synaptic connections and induce fast synaptic changes in their postsynaptic targets, dopamine fibers are modulatory in nature and induce long-lasting inhibitory changes. If the latter fibers are increased in number, especially if the release of dopamine is increased under stressful conditions, then it would be increasingly difficult for amygdalar fibers to induce depolarization in GABA cells. Inhibitory activity in the larger circuitry would be diminished. We can imagine a scenario in which the amygdalar fibers continue to release glutamate, until the inhibitory effect of dopamine is overcome. It is well-known that excitatory activity generates an influx of calcium ions that have the ability to cause an uncoupling of oxidative phosphorylation in mitochondria. This change, in turn, could potentially result in oxidative stress and the apoptosis signaling cascade being activated and underscores the importance of understanding the convergent inputs to GABAergic interneurons and the manner in which they respond to stressful conditions. This model is predicated on the idea that the circuit will decompensate under stressful conditions if the stress is occurring at a critical stage of development when dopamine and amygdalar fibers have attained a level of innervations that can produce such changes.

Affective Disorders

With regard to the affective disorders, where more post-mortem work has been performed in the past 5 to 7 years, more has been learned about brain circuitry. Notably, the regions implicated in Schizophrenia also appear to be affected in Bipolar Disorder (Benes, Kwok, Vincent, & Todtenkopf, 1998; Benes, Todtenkopf, Logiotatos, & Williams, 2000; Heckers et al., 2002). This is entirely consistent with the idea that the same categories of behavior are affected in both disorders. Although the nature of the symptoms and course may vary considerably, it is not

difficult to conceptualize that brain regions involved in motivation, attention, affect, stress, and learning might also show abnormalities in Schizophrenia and Bipolar Disorder. Nevertheless, it seems likely that the affective disorders will involve, either directly or indirectly, disturbances in monoaminergic integration. With regard to the corticolimbic system, it will be important to assess whether and, if so, how these monoaminergic systems are altered in individuals with depression and/or mania. Using immunocytochemical techniques, the distribution of noradrenergic and serotonergic fibers can be analyzed with respect to discrete subregions, layers, and neuronal cell types. This information can, in turn, be used to interpret the results of receptor binding activity associated with each transmitter's system. For example, depressed patients have up-regulated serotonin (Meltzer & Lowy, 1987) and noradrenergic (Siever, 1987) receptor binding activity that becomes down-regulated when they are treated with antidepressant compounds (Charney, Menkes, & Heninger, 1981).

In this latter regard, several different mechanisms could potentially result in increased receptor binding activity: (1) decreased synthesis or release of norepinephrine and 5-HT, (2) an increased rate of transmitter inactivation following release, (3) an increase in the synthesis of receptor molecules (beta, or 5-HT₂), or (4) a decrease in the rate of degradation of the receptor molecule. Each of these mechanisms could, in turn, be either primarily or secondarily altered; that is, changes may arise either from an intrinsic dysregulation of the genetic mechanisms involved in their regulation or as a result of effects exerted by pre- or postsynaptic neuronal elements influencing the cell in which they are found. It will be of central importance to determine the *specific* genetic and cellular mechanisms through which the activity of the relevant transmitter system has been modified. It will also be important to assess when these changes may have appeared during the life cycle of an individual with a mood disorder. A neurodevelopmental strategy may then yield information that might eventually lead to preventive, rather than ameliorative, treatment approaches.

To understand the onset of psychopathologic states it is important to determine which corticolimbic regions show these latter changes, what types of neurons within these regions mainly account for the differences, and how the intrinsic circuits within each region have been altered as a result of such changes. In the intervening time, we have learned that subjects with Bipolar Disorder, like those with Schizophrenia, show decreases in the expression of messenger RNA for GAD65 (Guidotti et al., 2000; Heckers et al., 2002) and GAD67 (Heckers et al., 2002).

Additionally, presynaptic axon terminals containing GAD65 have been found to be significantly reduced in patients with Bipolar Disorder, but not those with Schizophrenia (Benes, Todtenkopf, et al., 2000), suggesting that neuronal cell death may be a feature of the latter, but less so in the former. In addition to cell counting studies, further evidence in support of this idea has come from a study showing an unexpected decrease of DNA damage, a marker for apoptotic injury, in Schizophrenia, but not Bipolar Disorder (Benes, Walsh, Bhattacharyya, Sheth, & Berretta, 2003). Consistent with this, a recent gene expression profiling study has demonstrated a marked up-regulation of genes associated with the apoptosis cascade in bipolar subjects, but not in schizophrenics (Benes, Burke, Matzilevich, Walsh, & Minns, 2004). The idea that Bipolar Disorder involves cell death to a greater degree than Schizophrenia is counterintuitive, given the chronic dysfunctional state that is typically found in Schizophrenia. This contrasts strikingly with the episodic nature of Bipolar Disorder and the characteristic return to normal baseline functioning following a manic or depressive episode.

Linking Risk Factor to Histopathologic Abnormalities

It will be essential to define what the risk factors for a particular illness are and whether they may be inherited or acquired. As previously discussed with respect to Schizophrenia, it is now widely believed that a genetically determined latent trait acting alone or in combination with an early brain insult may play an etiologic role in the occurrence of this disorder. Once the risk factors are specifically identified, it will be necessary to develop strategies that aim to elucidate the neurobiologic consequences for an individual who carries these risk factors—that is, how they might result in specific circuitry alterations within corticolimbic regions.

Genetic Traits

One approach that postmortem investigations can use to relate certain histopathologic abnormalities to a genetic risk factor for Schizophrenia is to carefully analyze the data observed in different subtypes of the disorder. For example, Schizophrenia both with and without superimposed mood disturbances may be variations of the same illness but with somewhat different patterns of inheritance. Bleuler (1952) was the first to suggest that Schizophrenia may be a heterogeneous group of illnesses, and the so-called Schizoaffective Disorder is probably one of its subtypes. A genetic

etiology has been suggested for Schizophrenia (Gottesman & Shields, 1972; Kendler, Gruenberg, & Tsuang, 1985; Kety & Matthysse, 1972; Kety et al., 1968), but Schizoaffective Disorder has not been extensively studied. It is possible that particularly severe affective disorder could give rise to a syndrome that, in many respects, is indistinguishable from Schizophrenia (J. J. Levitt & Tsuang, 1988). Family studies have shown different findings for the two types of Schizophrenia. For example, both affective disorder and Schizophrenia tend to occur among the family members of schizoaffective patients (Fowler, 1978; J. J. Levitt & Tsuang, 1988), and a prevalence for schizotypal personality and Schizophrenia has been found in the first-degree relatives of schizophrenics (Kendler et al., 1985). Thus, although genetic factors for the two disorders are different in some respects, they also seem to overlap. Schizoaffective patients are believed to represent a genetically heterogeneous group of patients, so it might be expected that a microscopic finding emanating from a heritable trait that is common to both disorders would be more striking in the schizophrenic patients without mood disturbances who might be considered genotypically more homogeneous. However, from the data reported for neuronal cell density in the anterior cingulate and prefrontal cortices (Benes et al., 1991), the opposite was true. In the latter study, the small neuron density was even lower in the schizoaffective group when compared to the schizophrenics without superimposed mood disturbances. This latter finding might therefore argue in favor of the lower density of interneurons not having arisen from a primary genetic defect, but rather from birth complications or some other environmental insult.

In the future, if microscopic analyses can demonstrate that an abnormality is present in schizophrenics and schizoaffectives but not in manic depressive illness, this could potentially lay the groundwork for identifying the effects of a putative genetic trait. The next step will be to assess what types of genes might be involved in generating such an abnormality and to begin the arduous task of using molecular genetic approaches to determine which products of gene expression are involved. Once the gene is identified, it will be necessary to establish what the gene normally encodes for and how this encoding process could go awry at specific developmental stages, and then produce an alteration of brain circuitry like that seen in the disorder. A general discussion of this goal is straightforward, but the specific details of how to do this are awesome in their implications.

Current approaches to the genetics of Schizophrenia deal with familial tendencies for particular characteris-

tics and as such are at the most gross phenomic level. Because our current understanding of human genetics is at a rather rudimentary level, it is difficult to identify the phenomic equivalents for particular genes. There are genes that encode for both structural and functional protein molecules, but there are also loci that regulate the transcription of these genes by either turning them on or shutting them down. Accordingly, an alteration in the phenomic expression of a particular gene in human subjects could arise through changes in its own nucleotide sequence or the sequence for sites that regulate its expression, the so-called switches. It will also be important to determine whether a genetic variant involved in a psychiatric illness is uniformly expressed throughout the central nervous system. It is theoretically possible that there may be regional variations in the degree to which an abnormal gene is expressed, an issue that derives from the unique neurobiologic properties of the central nervous system. For example, an abnormality related to the GABA system that results in excessive GABA receptor activity could arise from a primary defect in the structure of the receptor molecule and affect its affinity properties; alternatively, it could be derived from a change in the postsynaptic regulation of gene expression for this locus as the receptor undergoes a compensatory up-regulation. There could also be primary alterations in the mechanisms through which GABA-A receptor molecules are packaged and transported to the surface of neuronal cell bodies in the anterior cingulate cortex of schizophrenics. Alternatively, there could be a primary defect in the expression of glutamate decarboxylase, the enzyme that synthesizes GABA, and this could give rise to a decrease in the amount of GABA available to interact with the receptor. The latter situation would also result in a compensatory up-regulation of GABA-A binding that secondarily, but not primarily, produces a change in the regulation of expression for the receptor gene.

The finding of increased glutamatergic afferents in superficial layers of the anterior cingulate cortex could also be attributable to a primary gene defect. In this instance, however, it will be even more complicated to define the specific mechanisms through which such a change might arise, because there is little general information regarding the genetic regulation of neuronal differentiation and the establishment of connectivity during brain ontogeny. Thus, the elucidation of such mechanisms related to specific types of neurons and specific types of fibers is not likely to be forthcoming for some time. Nevertheless, we can look forward to a time in the foreseeable future when information of this type will begin to emerge and will be available

to developmental psychopathologists for the study of mental illness.

Acquired Risk Factors

The strategies required for assessing the role of environment in the occurrence of Schizophrenia and other mental disorders will, in some respects, be different from those needed for the genetic factors. In addition to human genetic studies, it will be necessary to use animal models to assess how various types of environmental perturbations may induce alterations of brain structure and function. Animal models of behavior relevant to psychiatry have distinct limitations; nevertheless, they provide carefully controlled paradigms for evaluating the role of certain acquired factors (Henn & McKinney, 1987), and a critical use of such models can provide meaningful information.

Many different types of acquired insult have been traced to the records of schizophrenic subjects, including prolonged labor, viral infections in utero, head trauma, and emotional trauma. The heterogeneity of these factors makes it difficult to model for an early insult, unless a common denominator to all can be established. As noted, stressful conditions of any type result in an elevation of adrenal glucocorticoid levels in the blood as part of a general adaptive response of the body. It seems plausible that early traumatic events of any type could potentially produce a generalized insult to the brain. It does not seem likely, however, that such events would be sufficient to explain Schizophrenia or other mental illnesses, because individuals exposed to even severe anoxia resulting in cerebral palsy do not show any increased risk for psychosis. Nevertheless, studies of the effects of pre- and postnatal exposure to glucocorticoids on the development of the corticolimbic circuitry will provide important insights into the role of early stress in the etiology of Schizophrenia.

With regard to affective disorders, environmental factors are also thought to play an etiologic role, and a variety of animal models have been proposed for the study of this relationship. These have included maternal separation (Jensen & Tolman, 1962), learned helplessness (Overmeier & Seligman, 1967), behavioral despair (Porsolt, Bertin, & Jalfre, 1977), and chronic unpredictable stress (Katz, Roth, & Carroll, 1981). Studies using these and other models have attempted to establish construct validity by measuring various neurochemical markers related to monoaminergic transmitter systems to determine whether changes similar to those found in depressed patients can be elicited. For example, with the separation model, low cerebrospinal

fluid (CSF) norepinephrine levels are thought to be a trait marker that predicts a greater vulnerability, and reduction of CSF hydroxyindolacetic acid (HIAA) may be a state marker reflecting the behavioral response to this experimental manipulation (Kraemer, Ebert, Lake, & McKinney, 1984). In contrast, the observation that a tricyclic antidepressant can reverse the potentiated response of such animals to subsequent separation (Kraemer & McKinney, 1979) suggests that this paradigm may also have predictive validity as a model for depression. None of these models is completely satisfactory, but they are powerful research tools for studying the role of environmental conditions in the occurrence of mental illness.

The Interactions of Genetic and Acquired Risk Factors

As suggested by Hebb (1949), the influence of environment on the occurrence of mental illness is probably dependent on the constitution of the individual on whom it is acting. In modeling developmentally for the etiology of mental disorders, it seems appropriate to postulate that an environmental factor will likely interact with constitutional factors to give rise to Schizophrenia, mood disturbances, and other psychiatric illnesses. Thus, a non-specific insult associated with the release of neurotoxic levels of glucocorticoids could result in a diffuse loss of neurons, although the specific loci for such loss may depend on other factors that impart a *selective vulnerability*. For example, with regard to Schizophrenia, a preexisting increase of glutamatergic afferents to superficial layers of the anterior cingulate cortex could potentiate an excitotoxic injury to neurons with which they interact. In the setting of a stress response, the increased levels of circulating glucocorticoids could provide a precipitant for the increased release of glutamate at NMDA-mediated synapses (Stein-Beheims et al., 1992). Selectively bred strains of rodents will be a potent research tool to investigate the interaction of environmentally induced stress on genetically determined vulnerability for various psychiatric disorders. For example, operant responses of alcohol-preferring and alcohol-nonpreferring rats are being characterized (Murphy, Gatto, McBride, Lumeng, & Li, 1989), and differential responses of various neurotransmitters in these strains are being identified (McBride, Murphy, Lumeng, & Li, 1990). Selectively bred recombinant strains of mice are also being developed for the study of depression (Beekman, Flachskamm, & Linthorst, 2005). This general strategy will undoubtedly provide im-

portant insights into the interplay of genetic vulnerability with environmental factors.

Critical Stages for the Development of Psychopathology

It has been recognized for some time that various mental disorders frequently show a characteristic age of onset. Most schizophrenic patients will first present with symptoms at approximately 15 to 25 years of age, and this observation has led to the suggestion that normal ontogenetic changes during adolescence and early adulthood could theoretically play a role in the appearance of schizophrenic symptoms (Benes, 1988). Empiric support for such a viewpoint comes from studies of monkeys that received unilateral extirpative lesions of the dorsolateral prefrontal cortex soon after birth. There was no difference in the performance of lesioned and unlesioned monkeys on the delayed response task following recovery from the surgical procedure (Goldman-Rakic, 1981). When both sets of monkeys were again tested at approximately 2 to 3 years of age (their equivalent of pubescence), the unlesioned monkeys showed an age-appropriate performance, but the lesioned monkeys now showed a marked impairment of performance on the same task (Goldman-Rakic, 1981). These results were interpreted as indicating that late postnatal changes in the dorsolateral prefrontal region of monkeys might have provided a framework in which the previously latent effects of the lesioning could become manifest. However, the nature of these putative ontogenetic changes is not understood. Possible alterations that could play a role in the onset of Schizophrenia include a defect of synaptic elimination, which normally occurs in the cortex between 5 and 15 years of age (Feinberg, 1982), or the maturation of the cortical dopamine innervation during adolescence (Benes et al., 1996).

As discussed earlier, it is also known that changes in the myelination of a key corticolimbic relay zone occur during adolescence and again during the 5th and 6th decades of life. The fibers showing these postnatal changes probably derive from the cingulate cortex and possibly also the entorhinal cortex (Benes, 1989; Benes et al., 1994), and all of these regions have been implicated by recent postmortem investigations in the pathophysiology of Schizophrenia. An increase in the velocity of conduction would occur on these associative fibers as myelin sheaths form. An increased release of glutamate at NMDA-mediated synapses would also occur in relation to the overall increase of associative activity within this corticolimbic relay zone. In the setting of in-

creased numbers of glutamatergic fibers into the anterior cingulate cortex, such changes elsewhere in the corticolimbic system could trigger an excitotoxic injury within this region. Thus, late postnatal changes in the maturation of the corticolimbic system could conceivably play a role in the appearance of schizophrenic symptoms during adolescence. As discussed earlier, most neurotransmitter systems, both intrinsic and extrinsic to the cortex, show appreciable postnatal changes and could create an overall environment that is permissive for the onset of Schizophrenia.

A neurodevelopmental approach to the study of mental illness will require that we obtain a clearer understanding of how various neurotransmitter systems may be undergoing normal ontogenetic changes during the critical stages identified for each illness. For example, with regard to the model of Schizophrenia described earlier, the glutamate and GABA systems both show extensive postnatal maturation up to and, in some cases, including adulthood. The dopamine system also undergoes extensive postnatal development. It will be important to know the extent to which the dopamine system interacts with the GABA (Benes et al., 1996; Verney, Alvarez, Gerrard, & Berger, 1990) and glutamate (Goldman-Rakic, Leranath, Williams, Mons, & Geffard, 1989) systems, and the degree to which such interactions could play a role in the etiology and/or treatment response of this disorder at different stages of the illness. Ultimately, abnormal interactions among these various neurotransmitter systems will be understood in relation to postnatal brain ontogeny and the complex symptomatology of the disorder.

With regard to mood disorders, maturational changes in both the noradrenergic and serotonergic systems also proceed well beyond birth and, at least in some cases, even into adulthood. If a genetic factor related to monoaminergic transmission plays a role in the etiology of the affective disorders, it will be important to define the critical developmental periods during which the expression of a relevant gene is switched on or off. Information of this type can potentially be related to periods of the life cycle when environmental factors might contribute to the actual development of a mood disorder in an individual with genetic vulnerability. The experiences of such a person could be learned through neuroplastic changes that give rise to permanently altered networks of associative connections. Because norepinephrine and serotonin have both been implicated in the establishment of cortical connectivity during ontogenesis as well as the pathophysiology of depression, an abnormal gene related to these transmitter systems could theoretically play a role in the acquisition of maladaptive responses, such as learned helplessness or sep-

aration sensitivity, in individuals with a selective vulnerability for affective disorder.

It is clear that late postnatal changes in the convergence of dopamine and serotonin fibers onto GABAergic interneurons can potentially help to lay the groundwork for the formation of both normal and abnormal wiring patterns in the corticolimbic system of the human brain. In those who carry the vulnerability for psychopathology, such changes may well contribute to the onset of mental illness during adolescence and adulthood. Our understanding of how these putative miswirings occur must rest on a solid neurobiological foundation, one in which the cellular and molecular mechanisms that control the plasticity of dopamine and serotonin fibers are better understood.

Molecular Mechanisms in Developmental Psychopathology

Future studies will consider the mechanisms that may be involved in the establishment of connections between monoaminergic fibers and intrinsic cortical neurons. Toward this end, there are several proteins that comprise a family of trophic factors, such as nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), and the neurotrophins NT-3 and NT4/5, that play a role in the differentiation, survival, and maintenance of central neurons (Caleo, Menna, Chierzi, Cenni, & Maffei, 2000). The effects of BDNF and NT-3 on long-term potentiation in the hippocampus are mediated, at least in part, through specialized receptors, called Trk B and Trk C (Bramham, Southard, Sarvey, Herkenham, & Brady, 1996). This suggests that trophic changes at the molecular level contribute to the learning and memory associated with hippocampal function. During development of the cortex, GABAergic interneurons show a marked up-regulation in the expression of the genes for BDNF, NT4/5, and Trk B. It is noteworthy that these changes are believed to contribute to the intercellular signaling that occurs in nearby neurons showing evidence of apoptosis (Wang, Sheen, & Macklis, 1998). In the nigrostriatal system, the expression of messenger mRNA for BDNF, NT-3, Trk B, and Trk C influences the differentiation of neurons; BDNF and Trk B also seem to work through a dopaminergic mechanism involving the D1 receptor (Jung & Bennett, 1996). Although BDNF and NT-3 are quite active during early development, they continue to play a role in the regulation of functions, such as long-term potentiation, during the adult period (Bramham et al., 1996; Castren et al., 1993). It will be important for future studies to focus attention on these various trophic factors

and their associated receptors so that we can learn more about the specific role that they may play not only in the differentiation of neurons, but also in the functional maintenance of mature synapses.

It will also be pertinent to consider what role trophic factors and/or their receptors might specifically play in the competition of 5-HT fibers with convergent dopamine (DA) inputs to GABA cells during the postnatal period. Under normal conditions, it seems reasonable to postulate that BDNF and/or its associated receptor Trk B, or possibly NT-3 and/or its receptor Trk C, might contribute to the establishment and/or maintenance of these monoaminergic connections with GABAergic interneurons. From the standpoint of normal development, it is possible that BDNF is synthesized and released by intrinsic cortical neurons, and, once in the extracellular space, this trophic factor could help to promote the apposition of DA and 5-HT fibers on their outer cell membrane. In other words, once released, trophic factors might be free to exert their action directly on dopaminergic fibers, particularly those that have the potential to sprout, when stimulated to do so by the appropriate molecular stimuli. In contrast, abnormal conditions may be associated with an inappropriate release of one or more trophic factors by intrinsic cortical neurons, and this could theoretically provide the setting in which aberrant connection patterns emerge. An alternative possibility is that the elaboration of trophic factors by intrinsic neurons is relatively normal in some forms of psychopathology; however, the expression of their associated receptors (e.g., Trk B or Trk C) on extrinsic fiber systems like those from the ventral tegmental dopamine neurons might be abnormal. Either way, the net result could be the formation of increased numbers of appositions on one cell type (in this case, GABA cells) if it is releasing excessive amounts of trophic factor(s) and decreased contacts with another cell type, for example, projection neurons, if these latter cells show a down-regulation of one or more trophic factor systems. If the dopamine fibers are subject to limitations in the amount of sprouting they can undergo, this may influence the number of Trk B or Trk C receptors expressed by them. A second type of intrinsic neuron, the pyramidal cell, might show the opposite effect: a proportionate decrease in the number of DA fibers forming appositions.

CONCLUSIONS

It is clear that our understanding of the development of psychopathology has benefited from the use of sophisticated molecular approaches to analyze the expression of genes.

Microscopic techniques, such as *in situ* hybridization and immunocytochemistry, have a high degree of spatial resolution and will complement more encompassing approaches of gene expression profiling and proteomics. Gene expression profiling makes it possible to examine the regulation of 30,000 or more individual genes and offers an extraordinary view of the dynamics of cell regulation in the corticolimbic system. Such techniques are freeing neuroscientists from the constraints of studying one gene or protein at a time and are making it possible to study the complex cascades of changes that are probably occurring within corticolimbic neurons during normal and abnormal postnatal development. Recently collected microarray data from a cohort consisting of normal controls, schizophrenics, and bipolars show dramatic changes in the regulation of signaling and metabolic pathways in the hippocampus (Konradi et al., 2004). In this study, marked reductions in the expression of genes representing the electron transport chain were observed in bipolar subjects. Rather surprisingly, schizophrenics did not show these changes, although further analysis of this database has revealed significant changes in a broad array of genes associated with calcium channels, monoamine and peptide G-coupled protein receptors, transforming growth factor beta (TGF β) and Wnt signaling, and ribosomal regulation (Matzilevich, Burke, & Benes, 2004). Particularly noteworthy is the fact that the apoptosis pathway containing 44 different genes was significantly altered in both Schizophrenia and Bipolar Disorder, with the latter showing increased and the former decreased expression of key genes associated with cell death.

Recent studies provide support for the idea that the dopamine and serotonin systems show a significant degree of convergence and plasticity in the cingulate cortex, and the degree to which this occurs is probably similar for both pyramidal cells and GABAergic interneurons. Particularly noteworthy is the fact that the dopamine system may be capable of considerable plasticity, at least until the start of the early adult period. If the dopamine system in the human brain exhibits similar characteristics, the maturation of the limbic cortex during adolescence and early adulthood may potentially provide a window of opportunity for the induction of abnormal interactions of the monoaminergic systems with one another and with their intrinsic cortical targets. Indeed, some experimental evidence suggests that exposure to adrenal steroids during the postnatal period can result in an increase of dopamine interactions with interneurons in the medial prefrontal cortex of rats also exposed to these hormones prenatally (Benes, 1997). For GABAergic interneurons, complex changes in the regulation of GAD have been observed; however, these

occur whether or not there has been exposure prenatally to adrenal steroids (Stone, Walsh, & Benes, 2001). Based on these studies, an important question to ask is whether pre- and/or postnatal stress might also result in an altered distribution of serotonergic projections in the anterior cingulate cortex, one that may be reciprocal in nature to that observed for the dopamine system. If this were the case, the activity of GABAergic interneurons would be compromised by the presence of excessive dopaminergic inputs that are inhibitory in nature and diminished serotonergic inputs that are excitatory in nature. Because a combination of pre- and postnatal stress is believed to play a central role in the pathophysiology of some neuropsychiatric disorders (Benes, 1997; Walker & Diforio, 1997), it is plausible that changes in the way these two monoaminergic systems interact with one another might ultimately influence the activity of the individual cortical neurons on which they both converge.

This model appears to have predictive validity in that individuals with Schizophrenia and/or Bipolar Disorder who have a higher expected occurrence of obstetrical complications may be more likely to have an excess number of dopaminergic inputs to GABAergic interneurons. Such patients typically benefit from major tranquilizers that block dopamine receptors, as well as benzodiazepines that enhance the activity of GABA at the GABA_A receptor. The model is also consistent with the fact that patients in the manic phase of Bipolar Disorder typically show an exacerbation of their symptoms with antidepressant medications. Because many of these drugs block the reuptake of serotonin, the model also predicts that the pyramidal neuron, if receiving an excessive excitatory input from this system, would show even more heightened activity.

All models have weaknesses, and the principal weakness of this model is the fact that there have not as yet been systematic studies of the effects of pre- and postnatal stress on the relative numbers of dopamine *and* serotonin fibers on pyramidal cells versus GABA cells using a colocalization technique. Monoamine G-coupled protein receptors, such as the dopamine D4 and 5-HT7 subtypes, are noteworthy for their high affinity for atypical antipsychotic drugs (Lane et al., 2004; Meltzer, 1994). As described earlier, these findings fit well with those obtained for parallel post-mortem studies showing changes in the both the D4 and 5-HT7 receptor subtypes. Although some aspects of the model are inferential in nature, others have been cross-validated using a combination of rat and human studies. Future studies should be directed at identifying further what effect stress might have on convergent dopaminergic and serotonergic fibers on target neurons of the cortex, how

this interaction may be influenced by exposure to pre- and postnatal stress, and how various psychotropic drugs may exert their action in relation to neuroplastic changes in these convergent monoaminergic fiber systems.

Overall, the study of abnormal conditions such as Schizophrenia and Bipolar Disorder in a neurodevelopmental context offers the potential to learn more about the structure and function of the human brain and how perturbations of its development during critical stages can result in dysfunction. Unlike Alzheimer's disease, where there is widespread degeneration of the corticolimbic system, these same regions in individuals with Schizophrenia and Bipolar Disorder show only minimal degrees of atrophy and/or neuronal cell death that is restricted to discrete loci, such as layer II in the anterior cingulate cortex and sector CA2 of the hippocampus. Similarly, these latter disorders seem to show subtle alterations in the pattern of connectivity between extrinsic and intrinsic neurons within complex circuits. By their very nature, the neuropsychiatric disorders provide a natural model system in which the wiring of the brain may be studied to understand how slight variations can result in profound disturbances of complex cognitive functions. It is in the area of gene expression that Schizophrenia and Bipolar Disorder show much more pronounced differences. In the years to come, it is reasonable to expect that our understanding of how the corticolimbic system is altered in Schizophrenia and Bipolar Disorder will continue to expand, and there will be important new insights into how the corticolimbic system is functioning under both normal and abnormal conditions (Deskin et al., 1981).

Ultimately, our understanding of the pathophysiology of psychiatric illness will have to take into account a complex interplay between the various risk factors for these illnesses and normal developmental changes in the brain. On the one hand, it is likely that a genetic factor and/or an acquired insult to the brain can alter normal brain development, perhaps focally or in a generalized way. On the other hand, once the brain of an individual who is at risk for a mental illness has been affected by environmental risk factors, then normal ontogenetic changes may trigger their expression during critical periods of postnatal development. The inherited risk factor for affective disorder is probably different from that for Schizophrenia, and the types of environmental factors that influence their expression may also be different. In applying a developmental approach to the study of Schizophrenia, mood disorders, and other forms of psychopathology that present during childhood, adolescence, and adulthood, it will be necessary to define the unique neurobiologic consequences of abnormal genes

found in relation to each of these illnesses and to establish an understanding of how the expression of such genes interplays with normal ontogenetic events during a critical period of life when an individual at risk for such an illness is apt to become symptomatic.

The influence of early nutrition on the developing brain has been an issue that has waxed and waned in scientific popularity over the past century (Susser & Stein, 1994). However, popular culture has recognized the importance of early nutrition in children's health for many years. The Nobel Prize-winning author Pearl S. Buck wrote about the devastating effects of starvation on young children in her 1931 classic book *The Good Earth*. In this novel, the first daughter of the main character is born at the height of a severe famine. Buck implies that the significant malnutrition the child endured early in life resulted in devastating brain damage, leaving her profoundly retarded.

Conditions such as phenylketonuria (PKU) illustrate the importance of nutritional factors in brain development. If not addressed, PKU can result in mental retardation (Huttenlocher, 2000; Sullivan & Chang, 1999). Individuals with PKU are unable to metabolize phenylalanine; the subsequent buildup of this amino acid during brain development results in a toxic reaction leading to brain damage (Huttenlocher, 2000). Reports hypothesizing a nutritional origin of some forms of mental retardation first appeared in the early 1950s, when researchers noted high amounts of phenylketones in the urine of some mentally retarded individuals (Huttenlocher, 2000). Subsequent investigations linked PKU to various neuropathologies, including diffuse white matter changes and reduced dendritic branching (Huttenlocher, 2000). Specific genetic disorders resulting in deficiencies of micronutrients (such as copper in Menkes disease), regional geographic deficiencies of trace ele-

ments (such as iodine and selenium), and low prenatal levels of maternal nutrients (such as folate and iron) have all been linked to severe neurological abnormalities and/or intellectual deficits (Hibbard & Smithells, 1965; Lozoff, 1989; Pharoah, Buttfeld, & Hetzel, 1971; Prohaska, 2000; Shim & Harris, 2003; Yi-Ming, 1996).

The famines and food shortages throughout Europe during the Second World War created an interest in studying the changes in psychological and physiological functioning caused by undernutrition (Keys, 1946; Pollitt, 1988). Although much of this research pertains to adults, it is pertinent here because children likely exhibit similar psychological consequences and, by affecting the psychological state of their caregivers, parental malnutrition may exert indirect effects on children regardless of their nutritional status (Brozek, 1990).

Keys and colleagues at the University of Minnesota exposed 36 healthy males to 6 months of semistarvation followed by 3 months of controlled rehabilitation (Franklin, Schiele, Brozek, & Keys, 1948; Keys, 1946). Results indicated that during the period of semistarvation, the participants became lethargic, apathetic, less sociable, uninterested in sexual activity, less alert (except with regard to hearing), and depressed. Although the participants complained about changes in mental alertness and inability to think cogently, researchers noted no decreases on tests of memory or intellectual ability. The participants in the study exhibited unusual behaviors involving food, such as compulsive gum chewing and coffee/tea drinking (up to 40 packs

of gum a day and 15 cups of coffee a day), “souping” (the practice of drinking the liquid in soup then refilling the bowl with hot salted water and repeating the process before eating the vegetables in the soup), and unusual eating habits, including novel spice concoctions, hoarding of food, and doting over every last piece of food on the plate. Many of the participants greatly increased their daily consumption of water and either began smoking or substantially increased the amount they smoked (Franklin et al., 1948). Finally, participants displayed numerous physiological reactions, such as decreased sensitivity to heat, increased sensitivity to cold, edema, skin discoloration, and reduced hair growth (Franklin et al., 1948).

During the controlled rehabilitation phase, participants were initially irritable and easily frustrated (Franklin et al., 1948). These effects were short-lived; however, weight gain and sexual interest did not immediately return to prestarvation levels. In fact, participants did not reach their prestarvation weight and level of physical fitness until almost a year after the conclusion of the semistarvation phase (Franklin et al., 1948).

These findings are important because they indicate that periods of substantial undernutrition in adults result in demonstrable (but reversible) alterations in behavior, physiology, and mood (Franklin et al., 1948; Keys, 1946). The reversibility of these symptoms suggests that, in adults, behavioral changes occur secondarily to disturbances in neurotransmitter systems. This conjecture is supported by work (with humans and animals) showing dietary manipulations resulting in rapid changes in behavior and concentration of specific neurotransmitters (Fromentin, Gietzen, & Nicolaidis, 1997; Gietzen & Magrum, 2001; Phillips, Oxtoby, Langley, Bradshaw, & Szabadi, 2000; Riedel, 2004; Pierucci-Lagha et al., 2004). In the developing brain, the effects of undernutrition may not be as amenable to rehabilitation because this condition likely impacts both neurotransmitter systems and neuroanatomic organization (Winick & Rosso, 1969).

Using a unique natural experiment, Stein, Susser, Saenger, and Marolla. (1972) investigated whether prenatal exposure to famine in the Dutch “hunger winter” of 1944 to 1945 adversely affected intellectual abilities in a sample of 19-year-old males. In September 1944, the Netherlands cooperated with Allied forces in an attempt by British paratroopers to force a bridgehead over the Rhine River (Stein et al., 1972, 1975; Susser, Brown, Klonowski, Allen, & Lindenbaum, 1998). The attempt failed, and in retaliation, the German army imposed a trade embargo on Holland. Unfortunately, even when the army lifted the embargo, previous railroad strikes and a severe winter that had frozen

the shipping channels resulted in serious food shortages in much of western Holland. At the height of the famine, daily food rations could be as low as 450 kilocalories per person, a quarter of the standard amount. The most significant period of the famine began in November 1944 and lasted until Allied armies crossed the Rhine and liberated Holland in May 1945. The severity of famine was indicated by a sharply increased death rate in the affected cities (many of these deaths were attributed to starvation), substantial (up to 25%) loss in body weight, and the occurrence of physical signs associated with severe malnourishment, such as osteomalacia and hunger edema (Stein et al., 1972, 1975).

This event was unique because it occurred at a specified time and place in a population that before and after famine had good nutrition, there was good reporting on food rations provided to the population, and excellent public health records allowed researchers to divide individuals into groups of varying exposures based on birth date and birth location. This natural experiment has generated numerous investigations on the effects of prenatal famine exposure on a multitude of psychological and medical variables.

Stein et al. (1972) grouped individuals into six birth cohorts based on their intrauterine exposure to famine: individuals born before the beginning of the famine, individuals prenatally exposed to famine in the third trimester only, individuals exposed to famine in the middle 6 months of gestation, individuals conceived during the famine and exposed in the first and second trimesters, individuals conceived during the famine and exposed during the third trimester only, and individuals conceived and born after the famine occurred. Stein and colleagues used Raven Progressive Matrices scores gathered at age 19 during military induction testing to compare these cohorts to control cohorts born during the same time frame in cities of similar size but not affected by the famine. The researchers failed to find significant declines in average IQ or increases in the rates of mild or severe mental retardation in the four groups prenatally exposed or in the one group exposed postnatally. Because many births occurred at home, the researchers could not evaluate the influence of prenatal famine exposure on the birthweight of the entire cohort; however, a subsample of births occurring in hospitals in the famine and control cities indicated no relationship of birthweight to IQ at age 19.

These findings cast doubt on the assertion that maternal malnutrition alone results in significantly lower intellectual abilities. However, the authors emphasize that their findings should not be generalized to chronically malnourished populations where the mother is likely to be malnourished before and after parturition, the child is at high risk

for postnatal nutritional deficits, or deficiencies in specific trace nutrients are common. The authors suggest that their findings reveal either a high degree of protection afforded to the developing child in utero or the considerable resilience of many children in the face of prenatal insult.

Over the years, many people have speculated that nutrition affects proximal behavior (e.g., sugar increases activity levels). Although careful research has not substantiated this particular assertion, there are many clearly documented short-term effects of specific nutrients (or substances) on behavior (Beyth & Baratta, 1996; Fernstrom, 2000; Fishbein & Pease, 1994; Lieberman, 2003). However, these acute effects are not the topic of this chapter. Rather, the discussion focuses on the effects of generalized malnutrition or specific micronutrient deficiencies on the developing brain and how these insults may contribute to the later emergence of psychopathology.

Before beginning the discussion in earnest, it is important to define several terms. First, in this chapter, *early undernutrition* refers to caloric restriction occurring prenatally (sometimes even prior to conception) or in the first few years of postnatal development (prior to age 3). Second, *undernutrition* or *malnutrition* (used interchangeably throughout) refers to a general reduction in caloric intake, also known as protein energy malnutrition (PEM) or macronutrient malnutrition. Nutritional deficits can refer to either PEM or deficits in specific micronutrients such as iron (Fe), Zinc (Zn), or iodine (I). Most of the extant research concerns PEM/undernutrition, and this is the focus of the first section of this chapter; each of these three micronutrients is briefly discussed near the end of the chapter.

An unambiguous definition of what constitutes psychopathology has proven elusive (Lilienfeld & Marino, 1999; Meehl, 1979; Wakefield, 1993, 1999) but is not necessary here. We refer to major mental disorders as listed in the American Psychiatric Association's (2000) *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV-TR*) as constituting a large subset of psychopathology pertinent to this discussion. Most research relevant to this review examines Schizophrenia/Schizophrenia Spectrum Disorders, internalizing disorders (such as major depression and anxiety disorders), and externalizing problems (such as Attention-Deficit/Hyperactivity Disorder [ADHD] and Antisocial Personality Disorder).

BASIC PRINCIPLES

When examining the effects of nutritional deficiencies on the developing brain and the role these may play in the gen-

esis of psychopathology, it is important to keep in mind several core principles. First, brain development occurs in overlapping but dissociable stages, and each of these stages may be uniquely vulnerable to injury (Honig, Herman, & Shatz, 1996; Monk, Webb, & Nelson, 2001; Morgane et al., 1993; Teicher, Andersen, Polcari, Anderson, & Navalta, 2002; Webb, Monk, & Nelson, 2001). These stages include neurulation, neurogenesis, proliferation, migration, differentiation, synaptogenesis, myelination, apoptosis, and synaptic pruning (Andersen, 2003; Monk et al., 2001; Webb et al., 2001). Disturbances in some of these processes are associated with neurobehavioral deficits—as in the nonverbal impairments and psychiatric symptoms seen in the leukodystrophies—or the hypothesis that aberrant synaptic connections play a role in the etiology of Autism and Schizophrenia (Innocenti, Ansermet, & Parnas, 2003; Keller & Persico, 2003; Percy & Rutledge, 2001; Rosebush, Garside, Levinson, & Mazurek, 1999; Van Geel, Assies, Wanders, & Barth, 1997).

Some of the initial processes of brain development (e.g., neurulation and neurogenesis) occur during a single early period, whereas other, later stages (e.g., myelination, apoptosis, and synaptic pruning) occur independently at different times in various brain regions (Monk et al., 2001; Webb et al., 2001). Thus, a brain structure/region will have its own time course through which development proceeds. Moreover, certain brain regions such as the hippocampus are more vulnerable to injury than other regions (Walsh & Emerich, 1988). Ultimately, the result of any insult to the developing brain depends on the time of onset of the insult and what developmental processes are occurring/brain structures are actively developing at that time, how innately vulnerable these processes/structures are to injury, and the magnitude of the insult (e.g., the severity and/or duration of the injury). Based on these variables, a particular deficiency can have different effects on the developing nervous system (Adams et al., 2000; Georgieff & Rao, 2001; Kretchmer, Beard, and Carlson, 1996; Morgane et al., 1993; Pollitt, 1996).

A second important principle underlying the current discussion is the concept that abnormal behavior (as in psychopathology) is the efferent expression of brain activity, and changes in neuroanatomy, neurochemistry, and neurophysiology can result in alterations in behavior (Brower & Price, 2001; Moffitt, 1993; Moffitt & Caspi, 2001; Nestor, Kimble, Berman, & Haycock, 2002; Pennington & Ozonoff, 1996; Raine, 2002). Thus, early malnutrition may lead to the expression of cognitive deficits and/or abnormal behavior stemming from alterations in fine neuroanatomy (delicate structures such as dendritic arbors and

white matter tracks), neurochemistry (disturbances in neurotransmitter systems), and/or neurophysiology (the functioning of ion channels and specific receptors; Arnold, 1999; Benes & Berretta, 2001; Bowley, Drevets, Öngür, & Price, 2002; Konradi & Heckers, 2003; Molnar, Potkin, Bunney, & Jones, 2003). Although specific findings (e.g., white matter abnormalities or increased receptor density in a certain region) are sometimes difficult to replicate in new samples, disturbances in these three broad domains are consistently associated with various forms of psychopathology (Dwork, 1997; Fletcher, 1998; Jones, 1997).

The last core principle running through this discussion is the concept that genes will likely prove to be the single most important long-term determinant of behavior; however, their expression can be modified (repressed or activated) by interaction with the environment (Bunney et al., 2003; Jacobs et al., 2002; Murphy et al., 2001; Rutter, Pickles, Murray, & Eaves, 2001; Rutter & Silberg, 2002; Slutske et al., 1997). Environmental influences causing anomalous neurological development (such as chronic and severe neglect or toxicity) can have especially salient and long-term effects (Barone, Das, Lassiter, & White, 2000; Castle et al., 1999; Schettler, 2001; Weiss, 2000). Similarly, nutrition is an important environmental factor that can affect the developing brain (Georgieff & Rao, 2001; Morgane et al., 1993; Morgane, Mokler, & Galler, 2002).

This does not imply that environmental insults such as malnutrition have uniform effects on people of differing genetic characteristics. It is plausible that individual differences in the capacity to maintain homeostasis in response to challenges (thereby allowing for reasonably normal development) and in—at present—poorly explicated concepts such as neurological integrity, plasticity, and resilience are genetically or experientially determined; such factors likely modulate the effects of environmental challenges such as undernutrition (Bhutta & Anand, 2002; Engle, Castle, & Menon, 1996; Morgane et al., 1993; Nelson, 2000; Sapolsky, 2001).

Furthermore, it is rarely the case that undernutrition exists independently of other risk factors such as maternal stress, genetic predisposition, poverty, and dangerous living conditions (e.g., poor sanitation or the presence of toxins such as lead; Guesry, 1998; Pollitt, 1969; Schettler, 2001; Snodgrass, 1994; Stein & Susser, 1985; Tanner & Finn-Stevenson, 2002; Trope, Lopez-Villegas, Cecil, & Lenkinski, 2001). Pollitt reported that in developing countries, children with the greatest nutritional deficits had the poorest living conditions (i.e., lack of running water or adequate plumbing, cramped housing, and large families). Thus, malnutrition may generally exert its effects by acting

in concert (additively or synergistically) with other risk factors (Guesry, 1998; Morgane et al., 1993, 2002; Stein & Susser, 1985; Zeskind & Ramey, 1981). For example, Caspi and coworkers (2002) found that abused children with a genotype leading to higher levels of a neurotransmitter-metabolizing enzyme (monoamine oxidase) displayed lower rates of antisocial behavior. The authors interpreted these findings to be evidence of a gene-environment interaction in which the genotype influenced an individual's response to a particular environmental stimulus. It is possible that analogous mechanisms or interactions could be at work in determining the outcome of early malnutrition.

OVERVIEW

The current chapter endeavors to examine the effect of early nutritional deficits on brain development and the role this may play in the emergence of psychopathology. We begin the discussion by examining the possible link between early nutritional insults and the development of psychopathology in the context of those studies that have specifically researched this question. After this, we step back and delve into investigations that look at the affects of early malnutrition on broader issues such as cognitive development in humans and developmental neurobiology. These factors are important because they characterize a developmental path (resulting from early malnutrition) in which psychopathology may exist as part of the milieu or which may increase an individual's risk for the later development of mental illness. The chapter concludes with a brief hypothetical discussion of potential causal mechanisms that may account for the relationship between early nutritional insults and the later development of psychopathology.

STUDIES ON PSYCHOPATHOLOGY

Studies in this section are presented with regard to the spectrum of psychopathology they examine. Thus, although research in this area is sparse, studies investigating the effects of early malnutrition on Schizophrenia or Schizophrenia Spectrum Disorders, externalizing disorders (e.g., ADHD, conduct problems, and antisocial behavior), and internalizing disorders (such as depression) are discussed. In addition to other researchers, Krueger and colleagues (Krueger, 2002; Krueger, Caspi, Moffitt, & Silva, 1998; Krueger, McGue, & Iacono, 2001) have proposed the broad dimensions of externalizing and internalizing to capture more accurately the structure of common mental disorders.

These dimensions are used in the current discussion for clarity and succinctness.

Despite numerous investigations into the cognitive effects of malnutrition on children, most of the research dealing with the effects of malnutrition on the development of psychopathology concerns individuals older than 18 years. This is a significant shortcoming in our knowledge in this area because many psychiatric disorders will likely prove to have developmental origins. Thus, it is probable that these conditions have perceptible manifestations during childhood and adolescence. Similarly, early malnutrition may influence the developmental course (e.g., age of onset, severity, or progression) of psychiatric disorders. Moreover, malnutrition may be expected to exert more powerful immediate effects on the developing brain—thereby suggesting the effects of malnutrition may be more salient in individuals younger than 18. Thus, children affected by early nutritional deficits may display additional or significantly different behavioral effects than mature adults (Keys, 1946). Furthermore, it is possible that some of the cognitive manifestations of undernutrition (discussed later) may have resulted from impairments secondary to various psychiatric symptoms such as inattention or anxiety.

Much of the information regarding the relationship between early malnutrition and later psychopathology comes from data collected on cohorts prenatally exposed to famine during the Dutch hunger winter of 1944 to 1945 (A. S. Brown et al., 1996; Butler, Susser, Brown, Kaufmann, & Gorman, 1994; Hoek, Brown, & Susser, 1998; Susser, Hoek, & Brown, 1998). As discussed previously, Stein et al. (1972) found no evidence suggesting decreased intellectual abilities or increased rates of severe or mild mental retardation following prenatal famine exposure. However, years later, E. Susser (the son of the original investigators) and his collaborators revisited the famine data to examine if individuals with a history of prenatal famine exposure exhibited higher rates of psychopathology in adulthood (A. S. Brown, Cohen, Greenwald, & Susser, 2000; A. S. Brown, Susser, Lin, Neugebauer, & Gorman, 1995; Hulshoff Pol et al., 2000; Neugebauer, Hoek, & Susser, 1999; Susser & Lin, 1992; Susser et al., 1996).

Several major admonitions regarding this natural experiment should be pointed out. First, the amount of food redistribution in families is not known (Stein et al., 1972). Thus, pregnant women who occasionally received greater rations might have been supplied more calories via sacrifice of other family members (Stein et al., 1972, 1975). Second, although probably not substantially significant, it is not known how much individuals supplemented their

diets with material such as tulip bulbs, which may have actually contained toxins (Stein et al., 1972, 1975). Third, these data represent a circumscribed episode of malnutrition with a previously well-nourished population who returned to this status following the famine. Therefore, these results should not be generalized to chronically malnourished populations—especially those with other substantial risk factors (Stein et al., 1972). Fourth, except for records indicating profession of father, there is no information regarding familial background. Finally, because many of the births occurred at home, it is impossible to gather information on birth or gestational complications, which, along with maternal infection and stress, may play etiological roles in the emergence of behavioral deficits and psychopathological conditions (Anand & Scalzo, 2000; A. S. Brown et al., 2000; Brown & Susser, 2002; McNeil, Cantor-Graae, & Weinberger, 2000; Teicher et al., 2002). Regardless of these essentially unavoidable imperfections, the studies discussed here provide valuable insights regarding the possible role of prenatal malnutrition in the emergence of later psychiatric disorders.

In an initial 1992 study, Susser and Lin found that women, but not men, exhibited an increased prevalence of Schizophrenia following prenatal exposure to famine in the first trimester. However, they obtained these results through a broad inclusion criterion (i.e., first trimester of gestation during periods of low food rations) and review of admission records to psychiatric hospital units from 1978 to 1989. Thus, they based exposure on a single criterion that may not have completely captured children who experienced the highest levels of exposure. Furthermore, individuals were at least 32 years old at the start of the review period. This age tends to be past the age that most males have their first psychotic episode; therefore, it is likely many men would have already made initial psychiatric contact prior to this age and were not rehospitalized during the review period (Brown et al., 1996).

In a more extensive follow-up investigation, Susser et al. (1996) used stringent inclusion criteria to define a “maximal exposure” cohort. The inclusion criteria for the other cohorts were the same as in the 1992 study. However, they defined the maximal exposure cohort to include only those individuals conceived at the height of the famine. This cohort consisted of individuals born when the general population exhibited increases in adverse health effects and new births demonstrated excess congenital malformations (which, according to Stein et al., 1975, are associated with severe prenatal starvation). These criteria ensured that the researchers dealt exclusively with the maximally exposed cohort (e.g., the cohort that underwent the most significant

early insult due to the famine). These restrictions led to the identification of a cohort born between October 15, 1945, and December 31, 1945 (Hoek et al., 1996, 1998; Susser, Hoek, et al., 1998). The authors extended the period of record review back to 1970, thereby more accurately reflecting lifetime history of psychiatric admission.

Based on these data, the researchers found a significantly increased prevalence of Schizophrenia in both males and females of the maximal exposure cohort. This cohort displayed a prevalence rate for Schizophrenia nearly 2 times higher than that of the unexposed cohort. Further, the other exposed cohorts did not differ in prevalence rate from the unexposed cohort. Susser et al. (1996) demonstrated these findings using a “narrow” and a “broad” diagnostic definition of Schizophrenia. Individuals in the maximal exposure cohort had a mother malnourished during the periconceptional phase, and their prenatal famine exposure occurred early in pregnancy, generally entirely within the first trimester.

Using magnetic resonance imaging, Hulshoff Pol and colleagues (2000) found increased brain abnormalities (specifically, focal white matter hyperintensities) in a subgroup of individuals from the maximal exposure cohort. They showed that individuals from this cohort diagnosed with Schizophrenia evidenced reduced intracranial volume compared to nonexposed individuals with Schizophrenia and nondiagnosed individuals with the same level of famine exposure. The authors speculated that the decreased intracranial volumes observed only in the famine-exposed individuals with Schizophrenia resulted from an interaction between genetic risk factors and early brain stunting caused by gestational malnutrition, eventually resulting in the development of Schizophrenia. They concluded that exposure to famine early in gestation is associated with increased focal brain abnormalities, possibly secondary to specific micronutrient deficiencies. In some individuals, these aberrations may result in a higher risk for developing Schizophrenia. The researchers urge discretion when examining their findings, stressing that they obtained the results using a limited number of participants and that other confounding factors could not be completely taken into account. Nevertheless, these data provide an initial glimpse into specific structural brain changes present following severe first trimester malnutrition.

Another study by the same group expanded their inquiry to determine if males conceived at the height of the hunger winter evidenced increased prevalence of Schizophrenia spectrum personality disorders (SSPD) as defined by the *International Classification of Diseases 6 (ICD-6)* (Hoek et al., 1996). This study used methodology similar to the

earlier study. Thus, the authors compared the maximal exposure cohort (see Susser et al., 1996, for a description of this cohort) to an unexposed cohort and a cohort with first trimester exposure but without maternal malnutrition at the time of conception. The authors obtained data regarding the diagnosis of SSPD from military induction records; thus, males only are represented.

The investigators found that, when compared to the other groups, the maximal exposure group demonstrated a higher prevalence of SSPDs. This increase appeared to be unique to SSPDs because the three groups did not differ from one another in the prevalence of psychoneurosis, that is, general anxiety. They noted that this relationship remains consistent when estimated socioeconomic status (SES) is taken into account. However, the authors hasten to point out that despite the increased risk in the maximal exposure group, relatively few individuals in the entire study actually met criteria for SSPD. Furthermore, they cautioned that despite the apparent care taken in making these diagnoses, no formalized diagnostic system existed at the time of these evaluations. To some extent, this caution should be applied to both of the studies previously discussed.

Using information obtained from birth and medical records in a population-based cohort born between 1924 and 1932 in Helsinki, Finland, Wahlbeck, Forsén, Osmond, Barker, and Eriksson (2001) reported on the relationship between factors indicative of prenatal undernutrition and the later development of Schizophrenia. This study found that children born to mothers with a low body mass index (BMI) prior to parturition, who were born with small placentas, and were below-average length and weight at birth, had an increased risk of developing Schizophrenia in adulthood. Furthermore, this study indicated that, independent of other predictors, children thin at 7 years of age had an increased risk for developing Schizophrenia in later life. The data also indicated that children short at birth who remained lean during childhood had a fourfold risk of developing Schizophrenia. The authors observed no differences in the risk for Schizophrenia between groups of varying SES, replicating findings from other studies.

The researchers argued that these results are consistent with the hypothesis that fetal and childhood factors (specifically undernutrition) play a role in the pathogenesis of Schizophrenia. However, given the relatively low and consistent prevalence of Schizophrenia in the population and the relatively high rate of early malnutrition, it may be more plausible to conjecture that early nutritional deficits act as predisposing or triggering circumstances. Regardless, this study suggests that malnutrition statistically increases the risk for later development of Schizophrenia.

Wahlbeck and colleagues (2001) suggest that, in their sample, nutritional status (based on maternal BMI, birth length, and slenderness in childhood) is independent of SES; however, they provide no evidence to bolster this claim. Thus, given the information available, it is impossible to discern if these measures reflect actual undernutrition or are simply corollaries of low SES or a genetic diathesis that increases risk for Schizophrenia.

Taken together, these studies suggest that the prevalence of Schizophrenia and SSPD increases in individuals who are exposed to severe malnutrition early in gestation. The findings of Wahlbeck et al. (2001) also provide evidence that Schizophrenia is (either directly or indirectly) related to suboptimal growth in utero through early childhood.

Hoek et al. (1998) speculated about potential mechanisms to explain the findings of their group. First, they noted that it was unlikely that this finding was related solely to nutritional restriction because, if such a correlation existed, one would expect to find significantly higher rates of Schizophrenia and SSPD in developing countries that commonly have serious food shortages. They indicated that it was more likely that the increased prevalence was related to a restriction in a specific micronutrient, stating that these types of deficiencies are frequently observed in both developed and developing areas. This explanation could also account for the apparent independence of SES and nutritional status described by Wahlbeck et al. (2001). This hypothesis could be investigated further by using animal models of specific micronutrient deficiencies occurring at circumscribed times during brain development that reflect a proposed pathophysiology of a disorder, for example, migration defects in Schizophrenia secondary to folate deficiency. This approach could be useful in elucidating the effects of micronutrient deficiencies on neuroanatomy, neurochemistry, and neurophysiology; however, it would fall short in illustrating possible behavioral correlates because there are currently no irrefutable animal models of mental disorders, especially Schizophrenia. Finally, Hoek and colleagues stated, their findings could have resulted from the increased level of birth complications and morbidity associated with early birth found in the most affected famine cohort. However, they noted that areas less affected by the famine experienced similar increases in obstetric complications without the concomitant rise in SSPD, making this potential confound less problematic.

Neugebauer and colleagues (1999) again used the Dutch famine data to investigate possible relationships between prenatal nutritional restriction and the subsequent development of Antisocial Personality Disorder (ASPD). The researchers used diagnostic information regarding ASPD

from Dutch military induction records. According to the authors, Dutch psychiatrists considered ASPD to include a constellation of behaviors such as aggression, history of criminal activity, disregard for the truth, impulsivity, volatile temperament, unreliability, and interpersonal difficulties. Furthermore, psychiatrists categorized individuals under the subclassifications of violent or nonviolent ASPD.

Results indicated that individuals exposed to severe malnutrition in utero during the first and/or second trimesters had an increased risk for the emergence of later ASPD (specifically violent ASPD) compared to either unexposed individuals, individuals with only moderate levels of caloric restriction, and individuals severely malnourished in the third trimester alone. Malnutrition remained predictive, even after they included other proven or potential risk factors (such as low social class, low IQ, and large sibship size), for ASPD in multiple regression equations. The authors comment that the most likely explanation for this pattern of results is the lack of a particular unspecified micronutrient during this critical period of brain development. They argue that similarities in infant morbidity between cases and noncases, specificity of time and place of the findings, and the lack of third trimester effects indicate that severe malnutrition (during the first/second trimester) supersedes other environmental insults. However, they also propose a possible mechanism in which malnutrition potentiates preexisting genetic or environmental vulnerabilities.

Using a cohort of low birthweight (LBW) children, Breslau, Chilcoat, Johnson, Andreski, and Lucia (2000) examined the relationship between LBW, soft neurological signs, and subsequent intellectual/behavioral functioning at ages 6 and 11. Soft neurological signs refer to a number of various subtle neurological abnormalities in sensory, motor, and integrative skills that do not significantly impact an individual's overall functioning but may still result in suboptimal abilities in these domains (Breslau et al., 2000). Of particular importance, soft signs are not thought to reflect focal brain damage but rather a diffuse neurological pathology resulting from a variety of sources, including genetic anomalies such as microdeletions or mosaics (Breslau et al., 2000). Furthermore, studies have linked soft neurological signs to early malnutrition and deficits in IQ and behavioral functioning (Breslau et al., 2000; Galler, Ramsey, Solimano, Kucharski, & Harrison, 1984).

Breslau et al. (2000) observed a relationship between LBW and the occurrence of soft neurological signs in which LBW children are nearly twice as likely to exhibit soft signs as normal birthweight (NBW) children. The researchers found a linear relationship between LBW and the frequency of soft signs. Thus, the lower a child's weight at

birth, the more likely he or she would display soft signs. Moreover, the data indicated that children evidencing soft signs consistently performed below average on tests of intellectual abilities regardless of birthweight; however, LBW children tended to score lower on the IQ test in general, thus indicating additive influences. They also found a relationship between soft signs in both LBW and NBW children and the occurrence of learning disorders (at age 11) and the occurrence of internalizing problems at age 6 and 11. In the LBW group, the investigators found a relationship between soft signs and the occurrence of externalizing behaviors, including attention problems, at age 6 but not at age 11.

Even though this study did not strictly deal with nutritional deficits, it is interesting because LBW and soft signs may be associated with undernutrition. This is particularly germane to the Breslau et al. (2000) study because many of the participants, especially those in the LBW group, lived in urban settings and came from low SES backgrounds and thus had an elevated risk for prenatal and/or postnatal malnutrition. Regardless of the nexus between LBW and soft neurological signs, the findings suggest that LBW children may be at increased risk for reductions in IQ, learning disabilities, internalizing problems, and, when younger, externalizing difficulties, including attention deficits. The reason for the apparent evaporation of differences in the externalizing domain may be increased levels of externalizing behaviors exhibited by the control groups (Moffitt, 1993) or the beneficial effects of behavioral/medical interventions.

In a follow-up to their 1986 study (to be discussed in a subsequent section of this chapter), Galler and Ramsey (1989) assessed a group of previously malnourished Barbadian children for symptoms of hyperactivity. Using parent and teacher reports, they found increased levels of hyperactivity and distractibility. These relationships remained consistent after taking into account environmental factors such as parental involvement, parental career/knowledge of the world, stability of the home environment, number of siblings, and quality of living conditions (e.g., quantity of modern conveniences and durability of dwelling construction). Furthermore, these results concur with earlier findings (Galler, Ramsey, Solimano, & Lowell, 1983), which suggested increased attention difficulties in previously malnourished children between 5 and 11 years of age. The current study revealed an increased prevalence of speech difficulties in the formerly malnourished children as noted by teacher report. However, difficulties with socialization, emotional reactivity, and immaturity previously observed in these children (Galler, Ramsey, Soli-

mano, & Lowell, 1983) were not seen in the current investigation. According to the authors, this may have resulted from slight changes in the assessment tools (necessary to reflect the older age of the children) or interventions targeted at ameliorating some of the effects of early malnutrition. If the latter is the case, it is meaningful because it suggests that some aspects of early malnutrition (e.g., social skills) may be more amenable to educational interventions than others (e.g., attention problems; Galler & Ramsey, 1989). However, it is possible that effects such as emotional instability are more characteristic of younger children who were previously malnourished and would disappear in older children regardless of interventions (Galler & Ramsey, 1989). A shortcoming of this study is the researchers' failure to control for intellectual abilities. Thus, it is unknown if the increased attention problems observed in the experimental group are a unique aspect of undernutrition in the 1st year of life, or are a corollary of the lower intellectual skills previously reported in these children (Galler, Ramsey, & Forde, 1986).

Although not as robust as the findings for Schizophrenia, these studies imply that pre- as well as postnatal malnutrition predisposes individuals for exhibiting a variety of externalizing behaviors. It is intriguing to speculate whether the brain is susceptible to insults causing externalizing behaviors for a longer period during development, or if there are distinct etiologies of externalizing disorders, potentially linked to disruptions at various stages of brain development. Nevertheless, this handful of studies provides an impetus for future investigations on the role of malnutrition and other neurobiological risk factors in the etiology of externalizing problems.

A. S. Brown and colleagues (1995) investigated the relationship between prenatal famine exposure and the later development of affective disorders (affective psychosis and neurotic depression). The researchers defined affective psychosis and neurotic depression in accordance with *ICD-9* definitions. Thus, individuals with affective psychosis displayed disturbances in mood (either depression or mania) accompanied by mood-congruent delusions, whereas individuals with a diagnosis of neurotic depression displayed disturbances in mood (including symptoms of depression and/or anxiety) but evidenced no psychotic symptoms. They formed the groups by matching birth date and location with psychiatric admission records from 1978 to 1991.

Prenatal exposure to famine in the second trimester increased the risk of developing affective psychosis in later life; however, the authors did not find increased risk of affective psychosis resulting from first or third trimester famine exposure. These results remained significant when

sex was taken into account; however, there was a significant interaction between sex and second semester famine exposure: Males but not females appeared to be at greater risk for developing affective psychosis after second semester famine exposure, whereas females had higher prevalence rates in general. The data indicated no increased risk of neurotic depression following prenatal famine exposure in any trimester or in either sex.

A possible reason for the disparity between the diagnostic categories may be that, when compared to neurotic depression, affective psychosis represents a more severe mood disorder with a greater risk of hospitalization. Furthermore, neurotic depression may be more likely triggered by life stressors, and thus differences between groups could be submerged by random variation in the population. A limitation of this study is that females usually begin exhibiting mood symptoms in adolescence. Therefore, effects of prenatal famine exposure may be observed in females if the researchers reviewed earlier hospital admission records. Additionally, A. S. Brown and his collaborators (1995) caution, their findings may not represent increased prevalence of affective psychosis, but instead may reflect increased need for hospital admission or delayed onset of symptoms in prenatally famine-exposed males. Nevertheless, these results suggest that males are at greater risk for developing serious mood disorders following significant midgestational malnutrition.

In a follow-up to their 1995 study, A. S. Brown and colleagues (2000) greatly increased their sample size by obtaining new diagnostic records. The researchers focused on unipolar and bipolar depression requiring hospitalization. Exposure to famine during the second and third trimesters related to increased hospital admissions in both males and females with unipolar and bipolar depression. The authors indicated that this effect was particularly robust if exposure occurred in the third trimester only. These results extend the findings of the 1995 study and suggest that prenatal famine exposure predisposes adults to develop serious mood disorders requiring hospitalization and characterized by either depression or mania/hypomania.

Thompson and his collaborators (Thompson, Syddall, Rodin, Osmond, & Barker, 2001) examined the relationship between LBW and the incidence of depression in old age. These investigators used data obtained from individuals born between 1920 and 1930 in the English county of Hertfordshire and who still lived in the area in the early 1990s. The authors assessed all of the participants for depressive symptoms using two measures (a self-report questionnaire and a semistructured interview) and simultaneously asked about confounding factors such as SES,

recent loss, general illness, and coronary heart disease (CHD).

This study found a relationship between birthweight and depression in late life: The lower a child's birthweight, the greater the risk for developing late-life depression. The findings were more robust in males and remained significant when the researchers statistically controlled for other complicating factors such as illness, SES, and bereavement. When they specifically took into account the occurrence of CHD (another risk factor for late-life depression), the relationship grew stronger. The research indicated that males with LBW but high weight at 1 year exhibited the highest risk for late-life depression; conversely, males with above average birthweight and comparatively low weight at 1 year exhibited the lowest risk for late-life depression. Thompson et al. (2001) conjectured that this pattern indicated poor prenatal nutrition followed by compensatory growth and good prenatal nutrition followed by a regression to the mean, respectively. Because this study focused on current and not early life depression, the results should not be generalized to depression occurring outside of old age. The authors suggested that their findings provide support for aberrant fetal programming (see the conclusion of this chapter) caused by undernutrition as the major factor contributing to the future development of depression.

In summary, prenatal malnutrition appears to increase the risk for developing internalizing disorders (specifically mood disorders). It is interesting that the risk period for exposure to malnutrition in the externalizing and internalizing domains may be later than for the Schizophrenia Spectrum Disorders. The stages of brain development affected during these periods of vulnerability concur with research on the neurological sequelae of these various psychopathologies and support the timing of onset and duration of insult hypothesis. For example, the research on Schizophrenia strongly suggests that malnutrition exerts its effects in early stages of central nervous system (CNS) development, neural tube formation, and initial neuronal migration, all of which have been implicated in the etiology of Schizophrenia (Arnold, 1999; LaMantia, 1999; Rioux, Nisanov, Lauber, Bilker, & Arnold, 2003; Susser, Brown, et al., 1998). The later period of vulnerability observed in externalizing and internalizing disorders suggests that malnutrition disrupts later processes of brain development such as neurotransmitter formation, late-stage migration, and gliogenesis. Abnormalities in these processes have been implicated in the etiology of externalizing and internalizing disorders (Bowley et al., 2002; Cotter, Pariante, & Everall, 2001; Jenike et al., 1996). Further, some conditions (such as Schizophrenia) may be associated with a relatively acute

injury, whereas behavioral disturbances in the externalizing and internalizing domains may be associated with insults extending over longer periods.

Despite the paucity of studies on this topic, the investigations undertaken with the Dutch famine cohort and similar samples suggest that early malnutrition increases the risk for the later development of mental disorders. Furthermore, this effect is not a general increase in vulnerability, but appears to depend on the timing and duration of the nutritional insult. Because the Dutch famine studies lack confounds such as social class, deprived environments, parental education, and extended postnatal malnutrition (which frequently accompany early malnutrition), they cannot be generalized to a chronically malnourished population. However, they provide strong support for the unique contribution of severe prenatal malnutrition in the emergence of later psychopathology.

Regrettably, few studies have addressed the role of postnatal or pre/postnatal malnutrition in the development of psychopathology. This is particularly disheartening because postnatal malnutrition is common throughout the world, and, as discussed later in the studies on cognition, it is likely that postnatal malnutrition is associated with deficits that differ from those of prenatal malnutrition.

The previous discussion suggests that early malnutrition may lead to the later development of psychopathology. Moreover, the expression of a particular psychopathology likely depends on when the insult occurred (e.g., prenatal versus postnatal or first versus second/third trimester). Another contributing factor (discussed in greater detail in the concluding remarks) is that malnutrition may exert its maximal effect if it occurs concurrently with another insult such as stress or toxicity.

Now that a plausible link has been established, it is necessary to take a step back to examine what may underlie the development of these conditions. We first examine human studies that have been designed to determine if early malnutrition results in adverse effects on cognitive/intellectual development.

PRIMER

Before beginning this section, it is necessary to note that human protein energy malnutrition or undernutrition rarely exists without concomitant micronutrient deficiencies (Gorman, 1995; Kretchmer et al., 1996).

Human Studies of Cognitive Development

One of the shortcomings of research on humans is the difficulty controlling for all potentially relevant variables, some-

times even known confounds. This limitation is particularly vexing in epidemiological research regarding the long-term consequences of early malnutrition. For example, as previously discussed, early malnutrition rarely occurs independently of other risk factors such as poverty (Engle et al., 1996; Pollitt, 1969; Stein & Susser, 1985; Tanner & Finn-Stevenson, 2002). Although there are statistical techniques that can help compensate for this comorbidity, one must still be careful when making inferences regarding experimental interventions or the interplay of particular risk factors. Secondly, many studies using a population-based design are unable to account for other known or conjectured risk factors such as genetic predisposition, parental education, maternal stress, chaotic home environment, or other complicating physical factors such as toxin exposure, infection, or birth complications (Grantham-McGregor, 2002; Pollitt, 1969). These caveats are not indictments of these types of studies, because what such studies lack in elegant controls they often make up for in direct relevance. However, the limited control over potential third variables should be kept in mind when evaluating such studies.

There are numerous studies detailing the effects of early malnutrition on human cognitive development (Georgieff & Rao, 2001; Gorman, 1995; Pollitt, 1988). Many of these studies were conducted in developing countries, where malnutrition (or, perhaps more frequently, undernutrition) is likely chronic and may span all of development—from the periconceptional phase to adolescence and young adulthood (Grantham-McGregor, 2002). Given the growing minority and immigrant populations of developed countries such as the United States and the fact that a vast portion of children worldwide suffer from early malnutrition, a careful consideration of these studies is warranted, even for those primarily interested in industrialized populations (Pollitt, 1994). Furthermore, knowledge of successful nutritional interventions in developing countries may help to improve current U.S. government programs such as the Women, Infants and Children (WIC) program (Pollitt, 1994; Tanner & Finn-Stevenson, 2002). It is useful to review this literature to provide insight into the broad behavioral effects of early malnutrition. Further, research has linked intellectual/cognitive deficits to various types of psychopathologies (Moffitt & Caspi, 2001). Although this link may not be causal, these conditions (i.e., cognitive abilities and psychopathology) may nonetheless be connected.

Studies on neurocognitive outcomes of children who suffered early malnutrition is presented in three sections: studies concerning prenatal malnutrition and effects of LBW (where the fetus is protected from certain environmental factors such as poverty), studies on postnatal or

combined pre- and postnatal malnutrition, and studies examining the effects of nutritional interventions with malnourished populations.

LBW children or children born small for gestational age (SGA) are usually the result of intrauterine growth retardation (IUGR), which is frequently associated with fetal PEM (Georgieff & Rao, 2001). Although nutritional deficits in SGA babies can result from poor maternal nutrition, they can also result from other gestational or fetal problems such as maternal hypertension, uterine infections, or genetic disorders (Georgieff & Rao, 2001).

Numerous studies have examined the neurocognitive functioning of SGA children (Georgieff, Hoffman, Pereira, Bernbaum, & Hoffman-Williamson, 1985; Low et al., 1982; Pollitt, 1996; Stein et al., 1972). Strauss and Dietz (1998), using data from the National Collaborative Perinatal Project, compared the intellectual performance and visual-motor skills of IUGR children with that of their same sex non-IUGR siblings and NBW children (without IUGR siblings). These researchers demonstrated that IUGR infants are usually born to shorter women who weigh less than the average female. Furthermore, this study revealed that NBW siblings of IUGR children were typically smaller than other NBW children, although they were not considered SGA. The authors found that, at 7 years of age, formerly IUGR infants with a head circumference significantly below normal or less than their siblings' evidenced reduced intellectual capacity and visual-motor skills compared to NBW children. However, the performance of IUGR children did not significantly differ from their non-IUGR siblings, although the data trended in this direction.

These findings suggest that reduced birthweight is a phenomenon considerably influenced by genetic factors, although it is possible that the NBW siblings were malnourished, albeit at a lesser level than their SGA siblings. Additionally, statistically correcting for genetic and environmental agents suggests that IUGR alone does not substantially contribute to the reductions in cognitive abilities noted in other studies. However, these data indicate that IUGR infants born with significantly decreased head circumference differ from the NBW population, other IUGR children without reduced head circumference, and their siblings in terms of their intellectual and visual-motor skills at 7 years of age.

In contradistinction to this study, Low and colleagues (1982) failed to find a relationship between IUGR and cognitive deficits. Their results indicated that IUGR children remained smaller than their peers at 6 years of age; however, the data revealed no significant long-term effects of IUGR on cognitive, motor, sensory, or language abilities. The IUGR group exhibited higher rates of certain difficul-

ties (such as increased language difficulties and a slightly higher fail rate in senior kindergarten), but these differences did not reach statistical significance.

The authors admitted that the small IUGR male sample may have limited statistical power to detect delays in language skills, and they rightly point out that all of the children in this study were full term, preventing generalization to preterm IUGR infants. Furthermore, this study did not assess specific neurocognitive functions (e.g., attention and recognition memory) that, because of their mediation by the hippocampus, might be more susceptible to prenatal insults such as IUGR. It is also possible that intervening environmental factors (such as a quality home environment) attenuated deficits in IUGR children. Another explanation rests on the fact that the authors meticulously matched the IUGR and control groups on factors such as obstetric complications, newborn characteristics, socioeconomic variables, and status at 1-year follow-up; thus, factors potentially contributing to the reduced cognitive performance of IUGR children in previous studies might have been eliminated in the present investigation. Moreover, although not expressly stated in this paper, it is probable that the children in both IUGR and control groups received adequate postnatal nutrition.

Other studies have expressly examined the effects of decreased head growth and caloric restriction on cognitive skills (Georgieff et al., 1985; Harvey, Prince, Bunton, Parkinson, & Campbell, 1982). Winick and Rosso (1969) demonstrated that children dying of severe malnutrition in the 1st year after birth evidence reduced brain DNA content, indicative of fewer neuronal and glial cells. Reduced head growth secondary to reduced cell numbers is an important variable to consider because microcephaly (severely reduced head size) is linked to neurodevelopmental disorders such as Fetal Alcohol Syndrome. Furthermore, some investigators have correlated small head circumference at birth with greater risk for developing psychiatric disorders such as Schizophrenia (Archibald et al., 2001; Bracha et al., 1995; Kunugi, Takei, Murray, Saito, & Nanko, 1996). Although reduced head growth is not associated with development in a specific brain region, it may be an indirect indicator of general brain maturation (Pollitt, Mueller, & Leibel, 1982).

Georgieff et al. (1985) showed that SGA infants and infants who were a size appropriate for gestational age experiencing a prolonged period of postnatal caloric deprivation (due to medical complications) exhibited reduced rates of catch-up head growth. As would be expected, SGA infants began showing this reduced growth rate after sustaining a shorter period of caloric deprivation. The reduced rates of catch-up growth in these infants

resulted in smaller head circumference at 1 year, head growth curves that (although broadly within the normal range) continued to be less than optimal, and, in the most severely affected infants, below average motor development scores.

Harvey and colleagues (1982) found that children born SGA with intrauterine head growth that slowed prior to 26 weeks gestation obtained lower scores on tests of perceptual and motor skills at 5 years of age. SGA children with normal head growth performed at the same level as controls in these and other cognitive domains. The researchers combined the two SGA groups and evaluated performance strictly in terms of birthweight, ignoring rate of head growth; they determined that (taken as a single group) SGA children did not perform significantly differently from controls. Although this study did not deal with frank undernutrition, these results are an interesting corollary to the findings of Georgieff et al. (1985) because they indicate that early rate of head growth may have a long-term impact on certain cognitive abilities.

Although not entirely consistent, these studies suggest that SGA infants, especially those with decelerated rates of head growth, and children who have lower birthweight compared to siblings are at higher risk for developing subtle but detectable neurocognitive difficulties (Georgieff et al., 1985; Harvey et al., 1982). In addition, Tirosh, Gaster, Berger, Cohen, and Scher (2000) showed that birthweight and head circumference of typically developing children positively and significantly correlated with activity level and mobility in infancy. However, prenatal malnutrition in the absence of other risk factors has not been convincingly demonstrated to result in long-term decreases in cognitive abilities. It remains unclear how meaningful any deficits will be as previously malnourished children age (Guesry, 1998; Pollitt, 1996; Stein et al., 1972; Stein & Susser, 1985). Nevertheless, the relationship noted by Tirosh et al. is important because it suggests that babies born with low birthweight are less active and less able to explore their environment, thereby potentially reducing mental stimulation, which human and animal studies indicate is necessary for basic cortical organization and development (Black, 1998; Nelson, 1999). Researchers theorize that environmental stimulation is also critical for the development of other, more complex cognitive skills (Black, 1998; Nelson, 1999, 2000).

It is necessary to qualify these assertions. First, it is quite likely that the SGA infant is affected by the internal and external environments into which she or he is born, for example, by such factors as maternal substance use, stress, and genetic constitutions; postnatal nutritional factors; and

birth complications such as premature birth, hypoxia, and maternal infections. Therefore, the ultimate effects of SGA are likely graded on a continuum, depending on the combination of other vulnerabilities and assets possessed by the child (Engle et al., 1996; Stein & Susser, 1985).

Second, as stated previously, SGA infants are a heterogeneous group, and it is plausible that different etiologies of IUGR have different effects on neurological development (Black, deRegnier, Long, Georgieff, & Nelson, 2004). Finally, evidence suggests that prenatal malnutrition (especially if endured early in pregnancy) can occur without resultant low birthweight (Heasman, Clarke, Stephenson, & Symonds, 1999; Lumey, 1998). Lumey determined that prenatal malnutrition restricted to the first trimester resulted in compensatory placental growth without subsequent reductions in birthweight. For this reason, normal birthweight does not necessarily indicate the presence of adequate prenatal nutrition.

Thus, many children, despite being born the appropriate size for gestational age, may have sustained neurological insults due to prenatal malnutrition. These children, as well as SGA children, may be more vulnerable to further nutritional deprivation or other environmental insults (Berkman, Lescano, Gilman, Lopez, & Black, 2002; Galler et al., 1986; Galler & Ramsey, 1987, 1989; Ivanovic et al., 2000, 2002; Liu, Raine, Venables, Dalais, & Mednick, 2003). It is therefore difficult to dissociate the precise effects of prenatal malnutrition because the populations typically studied may not represent all prenatally malnourished individuals.

In a series of papers, Galler and colleagues (Galler & Ramsey, 1987, 1989; Galler, Ramsey, Solimano, & Lowell, 1983; Galler, Ramsey, Solimano, Lowell, & Mason, 1983; Galler et al., 1986) described the consequences of moderate to severe malnutrition sustained by Barbadian children in the 1st year of life. Galler et al. (1986) showed that, despite apparently successful nutritional rehabilitation, previously malnourished children continued to exhibit lower performance on tests of intellectual abilities up to 8 to 14 years postmalnutrition. In this study, researchers administered to participants the Wechsler Intelligence Scale for Children-Revised (WISC-R; Galler et al., 1986), and the participants' mothers completed a questionnaire assessing living circumstances, education, family relationships, and caregiver contact, among other factors. Consistent with previous evaluations (Galler, Ramsey, Solimano, Lowell, et al., 1983), results indicated that previously undernourished children had lower overall intellectual abilities and performed below controls (matched on birthweight, medical illnesses other than malnutrition, age, sex, and handedness) on the verbal and performance subscales of the

WISC-R. The researchers observed no sex differences or sex-nutrition interactions, except that (regardless of early nutritional status) females outperformed males on the Freedom from Distractibility index.

Galler et al. (1986) reported a significant correlation between scores on the WISC-R and environmental factors (e.g., poverty and maternal employment). However, early malnutrition remained significant when the authors statistically adjusted for these influences. Conversely, environmental factors remained significant when the authors statistically adjusted for early nutritional status. The significant influence of environmental factors on test performance at these older ages is interesting because this was not found in previous investigations with this cohort (Galler, Ramsey, Solimano, Lowell, et al., 1983). The authors concluded that a history of malnutrition continues to play a role in intellectual deficits at least into adolescence. However, as a child matures, the effects of an early nutritional insult may be overcome or attenuated by other environmental factors. Thus, the findings suggest that appropriate interventions may be effective in combating some of the intellectual impairments incurred in early malnutrition.

Using this same cohort, Galler and Ramsey (1987) found that previously malnourished children younger than 14 displayed deficient performance on Piaget's tests of conservation. These differences were not entirely accounted for by IQ, suggesting that these tasks assess slightly different cognitive domains. In contrast to the persisting differences on measures of IQ, previously malnourished children performed equivalent to controls by age 14. This pattern is similar to that observed in the Galler et al. (1986) study in that it suggests that effects of an early nutritional insult, initially very salient, grow less robust with time.

Another series of papers by Ivanovic and collaborators (Ivanovic et al., 2000, 2002) investigated the effects of severe early malnutrition on scholastic achievement, IQ, and brain morphology in Chilean high school graduates. Formerly undernourished and never undernourished high school graduates of low SES participated in this study. Researchers found that individuals with a history of early malnutrition obtained lower Full-Scale IQs (as assessed by the Wechsler Adult Intelligence Scale [WAIS]), lower scores on a scholastic aptitude test containing verbal and numerical items, and reduced brain volume on magnetic resonance imaging (MRI). The IQ results remained consistent across verbal and nonverbal domains in both sexes, whereas the brain volumetric difference, though significant in both sexes, emerged much more strikingly in males.

In a subsequent study with a similar population, Ivanovic et al. (2002) evaluated two groups of young adults

with mean IQs of about 125 and 91, respectively. Both groups included individuals of high and low SES. They assessed participants with the same battery as in the 2000 study, now adding intellectual testing of both parents. The researchers verified the occurrence of malnutrition in the 1st year of life by reviewing hospital records. The results indicated that, regardless of SES, children with higher IQ had greater brain volume, higher maternal IQ, better prenatal nutrition as indexed by birthweight, no evidence of postnatal nutritional deficits, and higher scholastic achievement. Maternal IQ, brain volume, and postnatal nutrition significantly related to young adult IQ. Early malnutrition rarely occurred in the high SES, low IQ group; however, this group evidenced lower maternal IQ when compared to the high SES, high IQ group. Conversely, 64% of individuals with low SES and low IQ had a history of early malnutrition, and this group, in general, had maternal IQs lower than the other three groups. Additionally, the individuals in the low IQ group had similar maternal IQ, scholastic achievement, and brain volume. This led the authors to conjecture that these findings are typical correlates of low IQ.

Liu et al. (2003) conducted a very interesting study in which they assessed the effect of malnutrition at age 3 on cognitive skills at age 3 and again at age 11, while attempting to statistically control for various psychosocial risk factors (e.g., living circumstances, parental education, age of mother at time of birth, presence of mental illness in the mother, and number of children living in the home). Study participants included children living on the island of Mauritius and enrolled in the Mauritius Child Health Project, a prospective longitudinal study of children's physical and psychological health. At 3 years, children were assessed for several indicators of malnutrition: angular stomatitis, kwashiorkor, sparse fine hair, and anemia. These indicators are associated with deficiencies in vitamin A and B₂; protein, zinc, and copper; protein energy, zinc, and iron; and iron, respectively. The researchers considered a child malnourished if he or she displayed one or more of these four indicators. Assessments at age 3 included subtests from the Boehm Test of Basic Concepts-Preschool Version. Assessments at age 11 included subtests from the WISC, Trails A & B (tests of executive functions), and a test of basic reading skills.

Results indicated that children malnourished at 3 years displayed overall intellectual and verbal cognitive deficits and continued exhibiting these deficits at age 11. Moreover, at age 11 these children exhibited deficits in nonverbal abilities, scholastic skills, reading abilities, and executive functioning. They found that even though

malnourished children tended to have lower parental education and higher scores on measures of social stress, the effects of malnutrition remained significant when these factors were statistically adjusted for in the analysis. Additionally, this study reported a dose-response (i.e., monotonic) relationship between indicators of malnutrition and cognitive skills, as assessed by the WISC. Thus, children with three of four indicators of malnutrition at age 3 had an IQs approximately 15 points below the mean, children with two indicators had an IQ 9 points below the mean, and children with one indicator had an IQ only 3 points below the mean.

The authors reported that anemia at age 3 years was the most significant indicator relating to lower cognitive performance at ages 3 and 11. The researchers acknowledged that they did not obtain nutritional information at age 11; hence, it is possible that these results could be explained by current or chronic malnutrition. Furthermore, the authors did not examine birth records. Therefore, factors such as birthweight and prenatal complications may have influenced the results. Nonetheless, this is a strong experimental design supporting the hypothesis that postnatal malnutrition has repercussions for later cognitive functioning. It also suggests that trace nutrients such as iron are particularly important in the manifestations of malnutrition.

The unique impact of postnatal malnutrition and its relationship with other risk factors on cognitive development remains unknown. In general, the studies presented here suggest that postnatal malnutrition is associated with discernable decreases in intellectual abilities (Berkman et al., 2002; Galler et al., 1986; Galler & Ramsey, 1987; Liu et al., 2003). Even though this assertion appears supported by the extant data, cautions similar to those detailed in the section regarding prenatal malnutrition still apply. For example, many of these studies did not directly assess potential confounding factors commonly associated with early malnutrition, such as parental IQ, biological risks (birth complications, childhood diseases, or environmental toxins), and social variables (such as a chronically neglectful or understimulating environment; Berkman et al., 2002; Guesry, 1998; Liu et al., 2003; Pollitt, 1969; Stein & Susser, 1985). Nevertheless, a majority of the studies indirectly assessed important variables and controlled for these variables in their subsequent analyses (Berkman et al., 2002; Galler et al., 1986; Galler & Ramsey, 1987; Liu et al., 2003), allowing us to be fairly confident in the assertion that postnatal malnutrition exerts deleterious effects on the developing brain.

The studies reviewed above continue to leave open the question of amelioration of the effects of early malnutri-

tion on the developing brain. Several studies addressing this point are considered next.

Generally, studies that examine amelioration of early malnutrition investigate either strictly nutritional or combined environmental/nutritional interventions (Joos, Pollitt, Mueller, & Albright, 1983; Lien, Meyer, & Winick, 1977; Pollitt, 1996; Raine, Mellingen, Liu, Venables, & Mednick, 2003; Raine et al., 2001; Winick, Meyer, & Harris, 1975; Zeskind & Ramey, 1981). The individuals in these studies are usually assumed to suffer from postnatal malnutrition, although many of the investigations did not explicitly rule out the possibility of prenatal nutritional restriction.

Pollitt and his collaborators (Pollitt, Gorman, Engle, Martorell, & Rivera, 1993) described a nutritional intervention in four rural Guatemalan villages. Beginning at various times during development (e.g., before conception, during gestation, throughout lactation, and into childhood), this project provided pregnant mothers and their children with either a high-protein, high-calorie drink known as Atole or a low-protein, low-calorie drink known as Fresco. The researchers fortified both beverages with trace minerals. Individuals in two villages received the Atole drink and individuals in the others received Fresco. Children of low SES whose mothers received Atole during gestation and until at least age 2 outperformed their peers on tests of information processing, mental ability, and academic skills, and progressed further in school than children receiving Fresco. Low SES children with shorter and later (beginning at or after age 2) periods of exposure to Atole also benefited (scoring higher on tests of numerical and reading abilities and progressing further in school than their peers), although these findings were less striking. These results are interesting because they argue for a stable, long-term improvement in intellectual, academic, and cognitive skills resulting from prenatal through postnatal nutritional supplementation in undernourished populations. Moreover, they imply that supplementation has the greatest impact/benefit on low SES individuals, perhaps because it delivers help to the children who, without it, would have fared worst. They also illustrate the differential vulnerability (or plasticity) of the brain depending on the timing of the insult and intervention.

Using data from the Mauritius health project, Raine et al. (2001) investigated the effects of an enriched educational environment on orienting and physiological arousal (measured by electroencephalography). In this study, experimenters matched children based on psychophysiological characteristics at age 3 and randomly assigned participants to an enriched preschool or a standard pre-

school educational experience on the island of Mauritius. The enriched preschool employed various types of enriching experiences, including well-balanced meals, education about nutrition and hygiene to parents and children, encouragement of imaginative play, interactive conversational skills, socialization, exercise, and regular field trips. Furthermore, parental involvement was highly encouraged, time-out discipline was used instead of corporal punishment, and the children's health was carefully monitored. The enriched experiences lasted for 2 years, at which time the children began grade school in typical classrooms.

Results indicated that the enriched preschool experience related to increases in orienting and physiological arousal at age 11. The authors speculated that these findings provided evidence of improved information processing or accelerated neurological maturation in children enrolled in the enriched preschool. They acknowledged that, given the multifactorial nature of the enriched experience, it was impossible to surmise which component or components explained these results, although research suggests that both nutritional and educational enrichment have unique effects on cognitive development (Grantham-McGregor, Powell, Walker, & Himes, 1991). However, these results may be explained by long-term changes in parental or child behavior caused by the early preschool experience. For example, the parental education and increased parental involvement encouraged by the preschool may have been built on and maintained after the child began grade school. Thus, the findings may represent the consequence of being raised in a more stable, lower-stress home environment and not by neurological alterations directly induced by the preschool experience. Regardless, these findings suggest that long-term alterations in physiological parameters, considered to reflect neuronal processing (Williams et al., 2000), can occur secondary to environmental enrichment and nutritional supplementation. These results are fascinating because reduced orienting and arousal responses are associated with various types of psychopathology (Banaschewski et al., 2003; Perry, Felger, & Braff, 1998; Schnur et al., 1999).

The previous studies illustrate the potential benefits of nutritional supplementation and combined nutritional/environmental enrichment in chronically undernourished populations. However, as discussed previously, undernourished children are frequently born with other genetic and environmental risks (Guesry, 1998; Pollitt, 1969; Stein & Susser, 1985). This begs the question: Can comprehensive environmental enrichment rescue a child with multiple risk factors, including malnutrition?

Winick et al. (1975) and Lien et al. (1977) addressed this question by investigating the intellectual performance of Korean children who suffered early malnutrition (prior to the age of 2) but were subsequently adopted into homes in the United States. Winick and colleagues showed that even the most severely malnourished children (below the 3rd percentile for height and weight at or before age 2) made significant advances in their physical and intellectual development after adoption. Specifically, in middle childhood, the previously malnourished children attained heights and weights above the standard for Korean children (although they continued to be smaller than American children). Furthermore, these children achieved IQ scores within the average range (mean of 102) and demonstrated academic performance comparable to their American peers. The researchers suggested that these scores were substantially greater (in excess of 40 points) than would be expected if these children remained in restricted environments. Of particular importance, this study showed a significant difference between the IQs of previously malnourished adopted children and those of adopted children with no history of malnutrition (mean IQ of the latter group was approximately 112). Winick and colleagues conjectured that these differences were partially genetic (the parents of undernourished children being more likely to have lower intellectual abilities), or a consequence of the nutritional deficits (i.e., the previously malnourished children had not been able to benefit as much from the adopted environment). Unfortunately, it is difficult to disentangle these possibilities without an assessment of parental IQ or a sibling design in which the other sibling was not malnourished.

In a study using a similar design, Lien et al. (1977) examined the roles of malnutrition on the cognitive development, growth, and academic achievement of Korean children adopted later in childhood (between 2 and 5 years of age). The researchers again found that severely, moderately, and nonmalnourished adopted children attained weight and height above standards for Korean children but below those of American children. However, they found that severely malnourished children attained IQ scores significantly lower than American children and their nonmalnourished adopted peers. Results also indicated that severely malnourished late adoptees had academic achievement scores below that of their American classmates and their late-adopted peers. The effect of nutritional deficits on academic performance remained significant when age of adoption and age of placement with the adoption agency were taken into account (this analysis was not completed on the IQ information because of the relatively small number of cases with this information provided). Interestingly, the

authors found a significant effect for age of adoption on academic performance, but no evidence relating academic performance to duration of malnutrition or for an interaction between any of these factors. Secondary factors (such as behavioral or emotional concerns) may explain both later age of adoption and below-average performance on IQ and academic tests, but more would have to be known about a child's preadoptive history to completely discount this confound.

These two studies provide evidence for improved cognitive and scholastic performance following severe malnutrition in adopted children removed from pathological environments. However, the results of the second study suggest that there is a critical period in which environmental enrichment will be maximally beneficial and after which recovery is either slowed or attenuated.

We have seen that environmental enrichment (of varying degrees and types) is able to ameliorate some of the detrimental effects of malnutrition on cognitive skills; however, a subsequent question asks, Would enrichment contribute to a reduction in psychiatric correlates of malnutrition? This is especially interesting because, based on the discrepant findings of Stein et al. (1972) and Susser et al. (1996) with regard to the effect of prenatal famine exposure on cognitive deficits and Schizophrenia, it appears likely that psychopathological conditions may be more sensitive to diffuse neurological disruptions than cognitive abilities, which themselves appear more sensitive than current measures of neuropathology.

In a follow-up to their 2001 study, Raine et al. (2003) address this question. This study reported that children who experienced the enriched preschool environment exhibited significantly fewer conduct problems and schizotypal personality traits at age 17 and reduced self-reported levels of criminal offending at age 23. Court records of criminal offenses trended toward fewer offenses in the enriched group, but this did not reach conventional levels of statistical significance. Furthermore, the data showed significant interactions between environmental enrichment and early nutritional status. Thus, individuals with poorer nutritional status assessed at 3 years of age (see Liu et al., 2003), prior to the enriched preschool intervention, demonstrated significant benefits from the program. Specifically, in addition to the results presented here, the undernourished group evidenced reduced interpersonal deficits at age 23 when compared to undernourished nonenriched controls. Subsequent analyses to account for psychosocial risk factors (see Liu et al., 2003) and physiological factors at age 3 revealed no moderating effects or changes in the re-

sults. The authors argue that their findings indicate long-term behavioral benefits of enriched environmental experiences and a particularly striking long-term improvement in functioning of previously malnourished children. They acknowledge that which aspects of the enriched preschool experience contributed the most to the observed differences cannot be identified. However, they contend that the improved nutrition offered by the preschool likely played a role, especially with regard to the children who had previous nutritional deficits. This hypothesis is consistent with the findings of other research studies indicating a unique effect of nutritional supplementation on cognitive development (Grantham-McGregor et al., 1991).

The studies reviewed here (in addition to many other investigations) suggest that environmental enrichment moderates the effects of malnutrition, albeit through direct supplementation or combined nutritional and educational enrichment. Some questions remain as to how permanent and significant these effects are, but certain data indicate that, if undertaken early in development and for a sufficient duration, the beneficial effects of environmental enrichment can become stable and long-lasting (Lien et al., 1977; Pollitt, 1996; Raine et al., 2001; Winick et al., 1975). However, it would be naïve to assume that all insults, regardless of severity or genetic diathesis, can be completely alleviated by high-quality schools, nutritional supplementation, and supportive parenting (Lien et al., 1977; Pollitt, 1996). No matter the interventions employed, one cannot help but suspect that some conditions remain resistant to complete amelioration. At the same time, the inherent adaptability and plasticity of the nervous system, both in children and adults, attests to the fact that some improvement in many conditions is possible, given proper stimulation (Huntley & Jones, 2002; Nelson, 1999). For example, the studies described by Pollitt suggest that in malnourished, low SES populations, nutritional supplementation alone can have a long-term ameliorative impact on cognitive functioning. Furthermore, the reports by Lien et al., Winick et al., and Zeskind and Ramey (1981) give hope that even individuals with risk factors across multiple domains can profit from quality environmental circumstances. Essentially, plasticity exists; however, recovery from early insults such as malnutrition is likely to be incomplete.

In summary, the studies discussed in this section indicate that early malnutrition has discernable effects on cognitive skills throughout all periods of brain development (gestational and postnatal). However, research also suggests that there is potential for catch-up brain growth and improved intellectual and behavioral development if

nutritional needs are restored. Additionally, other studies suggest that educational and environmental manipulations may also contribute to improved outcomes following early malnutrition. It is possible that some of the manifestations of malnutrition reported in this section (e.g., reductions in intellectual and certain cognitive abilities) may have resulted from impairments secondary to various psychiatric symptoms such as inattention or anxiety. However, with the exception of the Galler and Ramsey (1989) study, these two factors appear not to have been measured concurrently.

At this point, the discussion will again move down another level to focus on findings that shed light on the effects of early malnutrition on the structure and function of the developing and mature brain.

Neurobiology

Using a variety of dietary manipulations, many studies have linked early undernutrition to disturbances in neurotransmitter development and function and to neuroanatomic abnormalities, including fine structures (e.g., dendritic spines) and specific regions such as the hippocampus (Almeida, Tonkiss, & Galler, 1996; Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001; Morgane et al., 1993, 2002; Wauben & Wainwright, 1999; Wiggins, Fuller, & Enna, 1984). These are important factors to consider because changes in brain morphology and physiology caused by malnutrition may be similar to the biological alterations observed in various psychopathologies (A. S. Brown et al., 1996).

Neurotransmitters and their receptors are important determinants of brain development before they become a critical part of the information-processing activities of neurons (Benes, Bolte-Taylor, & Cunningham, 2000; Berger-Sweeney, 1998; Bonhoeffer & Yuste, 2002; Fernandez-Ruiz, Berrendero, Hernandez, Romero, & Ramos, 1999; Franciosi, 2001; Heine, 1999; Ma et al., 2000; Nguyen et al., 2001; Retz, Kornhuber, & Riederer, 1996; van Kesteren & Spencer, 2003; Whitford, Dijkhuizen, Polleux, & Ghosh, 2002). Thus, if early malnutrition disturbs the balance of neurochemical systems, it could result in structural and/or behavioral alterations (Alvarez et al., 2002; Wauben & Wainwright, 1999; Wiggins et al., 1984).

Disruption of neurotransmitter systems due to early malnutrition can directly or indirectly affect brain development (Wauben & Wainwright, 1999). That is, a neurotransmitter may directly induce a developmental process, for example, GABA in promoting proliferation of neuronal progenitors, acetylcholine's involvement in apoptosis,

serotonin's role in synaptogenesis, and glutamate's regulation of dendritic spine formation (Nguyen et al., 2001). Therefore, if early malnutrition greatly reduces or augments neurotransmitter concentration, normal processes may not occur, or may occur in an abnormal fashion (Wauben & Wainwright, 1999). Alternatively, a neurotransmitter may be responsible for modulating other neurotransmitters, growth factors, or signaling molecules (e.g., cytosolic calcium levels, immediate early gene expression, or the mitogen-activated protein kinase cascade), which in turn regulate other developmental processes (Wauben & Wainwright, 1999). All of these downstream events can be disrupted by abnormal neurotransmitter concentrations resulting from malnutrition (Evrard, Marret, & Gressens, 1997; Wauben & Wainwright, 1999).

The amino acids tryptophan and tyrosine are precursors of the neurotransmitters serotonin and dopamine, respectively (Benes et al., 2000; Wauben & Wainwright, 1999). The blood-brain barrier contains transporters for these amino acids, which are not directly synthesized in the brain (Wauben & Wainwright, 1999). Therefore, adequate dietary intake is essential to maintain proper CNS concentrations of these compounds. Serotonin is involved in neuronal proliferation and differentiation, glia formation, and synaptogenesis (Gaspar, Cases, & Maroteaux, 2003; Morgane et al., 1993; Okado, Narita, & Narita, 2001; Wauben & Wainwright, 1999).

Hernandez-Rodriguez and Manjarrez-Gutierrez (2001) found increased tryptophan uptake across the blood-brain barrier and serotonin synthesis within the brain of gestationally malnourished rats. They observed these differences through weaning, and the increased serotonin synthesis continued after nutritional rehabilitation and normalization of tryptophan uptake. Based on these animal studies and human research suggesting analogous patterns of plasma-tryptophan ratios, these researchers postulated that similar outcomes are likely in human infants suffering from prenatal malnutrition (see Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001, for review).

Manjarrez, Manuel, Mercado, and Hernandez (2003) conjectured that the increased concentration of serotonin observed in undernourished animals results in a desensitization of the serotonergic system secondary to chronic overactivation. Prenatally malnourished adult and adolescent rats also displayed decreased serotonin uptake sites, decreased serotonin fiber density, and enhanced serotonin release following hippocampal stimulation (Blatt, Chen, Rosene, Volicer, & Galler, 1994; Chen, Tonkiss, Galler, & Volicer, 1992; Mokler, Galler, & Morgane, 2003).

In addition, pre- and postnatally malnourished animals exhibit deficits in adaptation of the serotonergic system in response to chronic stress (Almeida et al., 1996; Mokler et al., 2003). Together, these results suggest that prenatal malnutrition can lead to long-lasting or even permanent alterations of the serotonergic system, potentially contributing to the later development of psychopathology (Benes et al., 2000; Fishbein & Pease, 1994; Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001; Manjarrez et al., 2003).

Pre/postnatally undernourished animals also demonstrate reduced reactivity to pharmacological manipulations of the catecholaminergic system (Almeida et al., 1996; Chen, Turiak, Galler, & Volicer, 1997; Soto-Moyano et al., 1999). For example, early malnourished animals showed an attenuated response to dopamine agonists that induced stereotyped motor behaviors, reduced sensitivity to cataleptic symptoms caused by dopamine antagonists, and a developmental delay in the induction of hypoactivity after administration of an adrenergic agonist (clonidine; Almeida et al., 1996; Bredberg & Paalzow, 1990; Goodlett, Valentino, Resnick, & Morgane, 1985). Other studies show decreased concentrations of dopamine and epinephrine receptors in specific brain regions of animals exposed to early undernutrition (Almeida et al., 1996; Wiggins et al., 1984).

Almeida and colleagues (1996) conjecture that these modifications are an adaptive response to initially high levels of catecholamines during brain development in undernourished animals. However, findings of increased sensitivity to the hypothermic effects of apomorphine (a dopamine agonist) but decreased sensitivity to the hypothermic effects of clonidine suggest a more complex picture in which pre/postnatal malnutrition has a differential impact on various subtypes of catecholaminergic receptors and on receptors within certain brain regions (Almeida et al., 1996; Brioni & Orsingher, 1987). For example, using a mild (8%) protein-depleted diet, Soto-Moyano and collaborators (1999) found increased norepinephrine release and neuronal density only in the occipital cortex of prenatally malnourished rats. Again, early malnutrition appears to cause alterations in the catecholaminergic system regardless of the precise dietary manipulation.

Prenatally malnourished animals exhibit reduced sensitivity to the effects of benzodiazepines (BZs; Almeida et al., 1996; Masur & Ribeiro, 1981; Tonkiss et al., 2000; Tonkiss, Trzcinska, Shultz, Vincitore, & Galler, 2000). This class of drugs potentiates the actions of the inhibitory neurotransmitter GABA (Almeida et al., 1996). Researchers observed long-term changes in sensitivity to BZs, similar to those found in the serotonergic system, during malnutrition and

following nutritional rehabilitation (Almeida et al., 1996; Tonkiss et al., 2000).

Tonkiss and coworkers (2000) studied spatial learning in prenatally malnourished rats following administration of the GABAergic agonist chlordiazepoxide (CDP) at 30 and 90 days after birth. They found that prenatally malnourished animals responded less than control animals to a high dose of CDP at both 30 and 90 days of age, but at 90 days, the previously malnourished animals displayed greater sensitivity to a lower dose of CDP when compared to well-nourished controls. A possible reason for these differential responses may be that the drug exerts certain effects (e.g., anxiolytic versus amnesic) at high and low doses. The researchers concluded that differences between the GABAergic system of malnourished and well-nourished animals resulted in differential responses to CDP depending on age of administration and particular dosage of the drug.

Researchers have linked early malnutrition to reduced levels of GABA transmitter and increased binding of GABA and BZs to the GABA receptor complex in the CNS of rodents (Almeida et al., 1996). It is probable that the alterations in GABA binding and concentration underlie the attenuated responses to BZs and result from permanent changes in this neurotransmitter system directly caused by early malnutrition (Almeida et al., 1996; Chang, Galler, & Luebke, 2003). Again, changes in this system appear consistent across dietary manipulations, ages, and strains of animals used; therefore, they likely represent actual effects of early malnutrition and are not simply a by-product of a specific experimental design (Almeida et al., 1996). Changes in the developing GABA system are significant because GABA is a very active transmitter in early cortical development (Ben-Ari, 2002; Davies et al., 1998).

Other rodent studies reveal that early malnutrition is associated with lower sensitivity to drugs acting on the opiate system; however, studies showing specific receptor changes have not been completed (Almeida et al., 1996). Similarly, studies indicate reduced cholinergic function in the early malnourished rats (Almeida et al., 1996). Specifically, differences in muscarinic receptor density, binding, and developmental course in different brain regions are seen in previously malnourished rats. However, too few studies have been completed to draw firm conclusions regarding the effect of early malnutrition on the cholinergic system with relevance to possible behavioral effects.

Tonkiss, Almeida, and Galler (1998) used an operant procedure to show that prenatally undernourished female rats displayed sensitivity to the blockade of glutamate receptors with an N-methyl-D-aspartate (NMDA) antagonist (MK-801). The NMDA receptor is a type of glutamate re-

ceptor highly concentrated in the hippocampus and is thought to play a critical role in learning and memory (Cui et al., 2004; Nakazawa et al., 2003; Roesler et al., 2003). Tonkiss and coworkers trained rats to a stable level of performance on a differential reinforcement of low-rates (DRL) task. On this particular DRL schedule, animals did not receive a reward unless they separated their responses by at least 18 seconds. After attaining a stable performance, the researchers administered MK-801 at various doses. Results indicated that the performance of prenatally malnourished female, but not male, rats was disrupted after MK-801 administration. This experiment is interesting because it is one of the few studies to examine sex differences in generalized prenatal malnutrition. Although speculative, the increased sensitivity to NMDA blockade in prenatally malnourished females may be the result of loss or dysfunction of NMDA receptors in the hippocampus of these animals (J. A. Salinas, personal communication, April, 2000). This explanation is consistent with histological findings in other neurotransmitter systems showing decreased concentrations of various receptor types following nutritional insults (Almeida et al., 1996; Wiggins et al., 1984).

Alternatively, Fiacco and colleagues (Fiacco, Rosene, Galler, & Blatt, 2003) reported that prenatally malnourished rats displayed persistent increases in the concentration of kainate receptors (another type of glutamate receptor) in the CA3 subregion of the hippocampus, a region implicated in recognition memory (Fiacco et al., 2003; Lee & Kesner, 2003). These differences persisted through 220 days of age, but they did not emerge until 30 days after birth. Furthermore, Palmer, Printz, Butler, Dulawa, and Printz (2004) found evidence of increased NMDA receptor binding in the striatum of prenatally protein-malnourished animals, but they observed no differences in NMDA receptor binding in the hippocampus or dopamine receptor binding in the striatum. These studies suggest that changes in the glutamate system occur in rats secondary to prenatal malnutrition; however, more studies need to be completed to specify the precise nature of these changes across brain regions, age, sex, and subtypes of glutamate receptors.

This research indicates that early malnutrition appears to perturb an animal's responsiveness to pharmacological manipulation of various neurotransmitter systems (Almeida et al., 1996). Many studies show decreased receptor density for several types of neurotransmitters (dopamine, epinephrine, serotonin, acetylcholine, and GABA; Almeida et al., 1996). Researchers postulate that this represents an aspect of homeostatic functioning in early malnutrition in that down-regulation of receptors occurs in response to higher

than normal levels of neurotransmitters during development (Almeida et al., 1996; Manjarrez et al., 2003). In addition, malnourished animals show decreased adaptations of the serotonergic and opioid systems in response to stress, possibly indicating permanently altered system dynamics (Almeida et al., 1996; Mokler et al., 2003). Essentially, malnutrition may exert its effects on neurochemistry not solely by affecting a single neurotransmitter system, but by perturbing the intricate balance between systems in the developing brain.

The changes in neurotransmitter systems described here appear to alter how an animal reacts and interacts with its environment. Therefore, if similar biochemical changes occur in the developing human brain, one could speculate that these perturbations will also result in modifications of behavior (Almeida et al., 1996). These behavioral changes may represent interesting correlates of certain forms of psychopathology (Almeida et al., 1996). For example, Almeida et al. (1996) reported on a study finding that, when compared to well-nourished controls, postnatally malnourished animals exhibited an anxiolytic reaction similar to that of Panic Disorder patients after chronic administration of either a tricyclic antidepressant or a monoamine oxidase inhibitor. Furthermore, numerous studies have linked dysfunction of neurotransmitter systems to the expression of various forms of psychopathology (Fishbein & Pease, 1994; Kaufman, Plotsky, Nemeroff, & Charney, 2000; Konradi & Heckers, 2003). In addition to effects on the organization of developing neurotransmitter systems, malnutrition (as noted earlier) affects structures in the brain such as the hippocampal formation. This brain region is particularly susceptible to a wide range of early insults and is implicated in various types of psychopathology (Arango, Kirkpatrick, & Koenig, 2001; DeBellis et al., 2000; Harry & Lefebvre d'Hellencourt, 2003; Heckers et al., 1998; Kimura, Reynolds, & Brien, 2000; Korte, 2001; Laakso et al., 2000, 2001; Walsh & Emerich, 1988).

Morgane et al. (2002) contend that early malnutrition results in decreased serotonergic innervation to the hippocampus due to decreased projections from the median raphe nucleus. However, as noted previously, early malnutrition results in increased serotonin release within the hippocampal formation proper. The authors propose that the disruption in input and local neurotransmitter concentration within the hippocampus leads to increased GABAergic activity in select inner neurons (Chang et al., 2003; Mokler et al., 2003; Morgane et al., 2002). Subsequently, this results in more inhibition of certain hippocampal regions, thereby potentially affecting information outflow and integration (Morgane et al., 2002).

Malnutrition results in deficits in long-term potentiation (LTP; Jordan & Clark, 1983), which is considered a candidate mechanism for learning and memory processes (Bliss & Collingridge, 1993; Kandel & Schwartz, 1982; Martin & Morris, 2002). Moreover, Morgane and colleagues (2002) stated that perturbations of hippocampal inhibitory mechanisms produce asynchronous activity of neuronal networks, potentially leading to decreased hippocampal plasticity (Morgane et al., 1993). Furthermore, Jordan and associates (Jordan, Howells, McNaughton, & Heatlie, 1982) suggested that malnutrition induces changes at the level of hippocampal synapses. In summary, early malnutrition appears to disturb hippocampal function through a variety of mechanisms (Morgane et al., 2002).

Early PEM is associated with a reduction in dendritic spine density and with abnormal spine morphology in the hippocampus, cerebral cortex, and cerebellum (Benitez-Briebesca, De la Rosa-Alvarez, & Mansilla-Olivares, 1999; Fiala, Spacek, & Harris, 2002). A dendritic spine is a plastic structure frequently found in the cortex and is thought to play an important role in stimulus encoding and information processing (Bonhoeffer & Yuste, 2002; Coss & Perkel, 1985; Fiala et al., 2002; Segal, 2001; Whitford et al., 2002). Specifically, malnutrition may result in anomalies of spine number and shape of pyramidal cells within cortical layers III and V and the CA3 region of the hippocampus and of granule neurons within the dentate gyrus (Fiala et al., 2002). Cerebellar granule cells, Purkinje cell spines, and giant spines are reduced in early malnutrition (Fiala et al., 2002). These findings are important because research indicates that dendritic spine abnormalities exist in conditions such as mental retardation (Fiala et al., 2002).

The previous discussion supports the assertion that early malnutrition can result in distinct changes in brain neurochemistry and delicate morphology (Almeida et al., 1996; Fiala et al., 2002). However, the process of brain development is likely significantly protected (through various homeostatic and placental mechanisms) from many harmful environmental influences. This being said, the developing organism can compensate only so much before long-term changes in the chemical composition or structural organization of the developing brain result. The precise nature and extent of these changes may vary among individuals, although some general patterns (such as elevation of neurotransmitter concentrations and pathological dendritic spine formation) likely exist.

Although specific pathological mechanisms explaining behavioral changes are unclear, developmental perturbations in neurochemistry, neurophysiology, and brain morphology resulting from early malnutrition implicate candidate mechanisms that could account for behavioral

deficits. Research indicates that chronic changes in various neurotransmitter systems can affect levels of growth factors, gene expression, functioning of other transmitter systems, and the ability to acquire certain types of learning (Dudman et al., 2003; Kesslak, Chuang, & Berchtold, 2003; O'Donnell, Stemmelin, Nitta, Brouillette, & Quirion, 2003; Paule et al., 2003). Researchers have identified all of these factors as necessary components of typical CNS development (Acampora, Gulisano, & Simeone, 1999; Bar & Goffinet, 1999; Black, 1998; Cirulli, Berry, & Alleva, 2003; Cowan, 1998; Lyons et al., 1999; Nelson, 2000; Rutter & O'Connor, 2004; van Kesteren & Spencer, 2003). Therefore, significant or persistent dysfunctions in these systems (secondary to early malnutrition) may contribute to abnormal neurological development. Work by Gietzen and others (Blevins, Teh, Wang, & Gietzen, 2003; Gietzen & Magrum, 2001; Gietzen, Ross, Hao, & Sharp, 2004; Jousse et al., 2004; Truong, Magrum, & Gietzen, 2002) reveals that reductions of specific amino acids result in altered gene expression and changes in various neurotransmitter systems. These cascading effects provide a plausible mechanism for the effect of macronutrient malnutrition on neurobiology and behavior; that is, malnutrition causes decreases in important neurotransmitter systems, thus resulting in changes in growth factor concentration and in gene expression, eventually leading to modifications of behavior.

The discussion in this section focused on generalized caloric restriction/macronutrient deficiency. The reason for this emphasis is practical in that this is where many researchers have concentrated their efforts. However, as noted in the introduction, certain micronutrient deficiencies are associated with deviant brain development. Therefore, although little research exists directly linking specific micronutrient deficiencies to psychopathological outcomes, it is important to review briefly some of the extant research concerning the effect of specific micronutrient deficiencies on brain development.

PRIMER

As stated previously, it is common for deficits in micronutrients to accompany generalized protein energy malnutrition (Gorman, 1995; Kretchmer et al., 1996); conversely, it is possible to have deficits in specific micronutrients without concomitant caloric or protein restriction (Brozek, 1990; Georgieff & Rao, 2001). The latter scenario is more common in developed versus developing countries (A. S. Brown et al., 1996). As discussed earlier, A. S. Brown and colleagues postulated that deficiencies in specific mi-

cronutrients (such as folate) more fully explain the findings in the Dutch hunger winter cohort. Numerous studies have repeatedly allied early deficits of iron, zinc, and iodine with aberrant brain development and decreased cognitive skills; thus, this brief discussion focuses on these elements (Georgieff & Rao, 2001; Kretchmer et al., 1996; Yi-Ming, 1996).

Some studies have stressed the necessity of adequate levels of other micronutrients (such as vitamin B-6, selenium, manganese, copper, and choline) for proper neuronal development; however, they have been studied less extensively, especially with regard to human brain development and cognition (Castaño et al., 1997; Craciunescu, Albright, Mar, Song, & Zeisel, 2003; Fisher, Zeisel, Mar, & Sadler, 2002; Guilarte, 1989, 1993; Groziak & Kirksey, 1990; Keen et al., 1999; McCullough et al., 1990; Prohaska, 2000; Watanabe & Satoh, 1994; Yi-Ming, 1996; Zeisel, 2000). However, several studies have linked decreased periconceptional folate concentration to the development of neural tube defects in the progeny of some individuals (Czeizel & Dudas, 1992; Hibbard & Smithells, 1965). A. S. Brown et al. (1996) conjectured an association between prenatal folate deficiency and the development of Schizophrenia. Furthermore, investigators have observed lower folate levels in depressed adults, but the etiology or significance of these reductions (i.e., if they represent a symptom of or a contributor to depression) is unknown (Alpert & Fava, 1997).

Iron

Iron deficiency (ID) is one of the most common forms of undernutrition in the world (Lozoff, 1989). It is caused by chronic malnutrition or consumption of foods low in dietary iron (usually the case in developing countries), or by conditions such as maternal diabetes or IUGR (usually the cause in developed countries; Georgieff & Rao, 2001; Petry et al., 1992). A significant body of work has connected early ID to disturbances in myelination, neurotransmitter systems, metabolism, and hippocampal morphological development (Beard, 2003; de Deungria et al., 2000; Jorgenson, Wobken, & Georgieff, 2003; Kwik-Urbe, Gietzen, German, Golub, & Keen, 2000; Lozoff, 1989).

Behavioral studies with animals have shown that perinatal ID results in impaired performance of hippocampally dependent tasks, lower environmental reactivity, and decreased motor skills (Felt & Lozoff, 1996; Schmidt, Waldow, Salinas, & Georgieff, 2004). Finally, studies conducted with ID infants and children have revealed deficits in motor skills, sensory processing, recognition memory, visuospatial abilities, language skills, attention, and academic

performance—some of which may persist after iron repletion (Lozoff et al., 2003; Lozoff, Jimenez, Hagen, Mollen, & Wolf, 2000; Nelson, Wewerka, Borscheid, deRegnier, & Georgieff, 2003; Roncagliolo, Garrido, Walter, Peirano, & Lozoff, 1998; Stoltzfus et al., 2001). Lozoff and colleagues (2003) contend that ID children are less socially interactive, display more inefficient information processing, and exhibit reduced activity in their physical environment. Thus, they conjecture that ID infants are less likely to receive sufficient environmental stimulation. Although some researchers have indicated that ID children display more anxious/withdrawn temperaments (Lozoff et al., 2003), no studies have expressly linked early ID to the later development of psychopathology.

Iodine

Iodine is a necessary component of various thyroid hormones. In the late 1990s, estimates indicated that approximately 1 billion people in the world were at risk for iodine deficiency (Yi-Ming, 1996). Severe maternal iodine deficiency in the preconception period (usually attributed to hypothyroidism) is associated with the development of severe mental retardation secondary to endemic cretinism (Pharoah et al., 1971). Moreover, moderately iodine-deficient children display minor (but significant) increases in reaction time and decrements on neuropsychological measures of verbal information processing, attention, and visual-motor integration (Fenzi et al., 1990; Lombardi et al., 1995). These studies suggested that the differences were time-limited and amenable to amelioration with iodine therapy. Additionally, periconceptional injection of iodized oil in at-risk populations is effective in attenuating the incidence of endemic cretinism and subsequent mental retardation (Pharoah et al., 1971). Conversely, prolonged childhood iodine deficiency may lead to lower achievement motivation and decreased learning speed, both of which become more striking with increasing age (Tiwari, Godbole, Chattopadhyay, Mandal, & Mithal, 1996). Again, no investigations have specifically examined any possible connections between early iodine deficiency and the development of mental illness (with the well-established connection between maternal iodine deficiency and mental retardation being the exception).

Zinc

Zinc is an important component of many enzyme systems and has been localized to presynaptic vesicles within limbic and cortical regions of the brain (Frederickson & Danscher, 1990; Johnson, 2001; Tuormaa, 1995). Zinc deficiency is associated with growth retardation and impaired hippocampal

functioning (Sandstead et al., 1998; Tuormaa, 1995). Zinc is also critical for axonal transport and proliferation during neuronal development (Tuormaa, 1995). Animals made zinc-deficient early in gestation commonly experience fetal reabsorption or spontaneous abortion (Tuormaa, 1995). Zinc deficiency in later gestation or during lactation results in decreased forebrain and hippocampal size as well as reductions in total cell numbers (Duamah & Russell, 1984; Tuormaa, 1995).

Some researchers have linked zinc deficiency to increased hyperactivity, apathy, lethargy, sleep problems, poor appetite, aggression, and irritability (Tuormaa, 1995). Others have hypothesized that maternal zinc deficiency during gestation results in permanent alterations of neurological development, which may eventually manifest as psychiatric or neurological conditions (such as Schizophrenia, Autism, epilepsy, and Parkinson's disease; Johnson, 2001). Despite the potential seriousness of zinc deficiency, a study by Sandstead and colleagues (1998) reported that zinc-deficient children showed improved neuropsychological test performance after 10 weeks of zinc supplementation, leaving open the possibility of successful zinc rehabilitation.

FUTURE DIRECTIONS

The research reviewed in this chapter indicates that malnutrition is associated with disturbances in neurotransmitter systems necessary for normal neuronal maturation, morphological changes in delicate brain structures, and reductions in brain growth. Functional behavioral disturbances include deficits in cognitive abilities and an increased risk for psychiatric disorders, including Schizophrenia and related conditions such as externalizing behaviors and internalizing difficulties. These form and function effects persist across various models of malnutrition in animal studies and across demographic factors (country of origin and social class) in human investigations.

Isolating the specific role played by early malnutrition in the development of psychopathology in humans remains difficult because of multiple covariants. However, the problem of early malnutrition is significant for both developed and developing countries; thus, additional research is necessary to better explicate the long-term consequences of this condition. A major issue that future research should specifically address is the significance (i.e., magnitude of the effect) of malnutrition in the development of psychopathology. Specifically, does early malnutrition independently increase the risk for the development of psychopathology, or is it merely

one of many important factors that, when combined, have a deleterious effect? The challenge lies in conjecturing plausible and testable mechanisms for these interactions and deriving maximally precise predictions of which factors contribute in which ways to the eventual outcomes. These are likely to be neurobiological models (concerned with cellular and molecular mechanisms) which then will inform behavioral models (tested on animals and concerned with negative correlates) based on extant relationships between form and function in the brain that are conserved across species. These studies would be complemented by statistical models that seek to explain population and subpopulation relationships among factors. Because criteria for the diagnosis of mental disorders is somewhat arbitrary and may be somewhat culturally determined, a possible way of examining this issue across settings may be to investigate more biological markers of mental disorders (such as dexamethasone suppression in depression). Although this particular test is far from perfect, this approach may provide a useful tool for examining the base rate of psychopathology in undernourished populations, where the current diagnostic system may be less effective for determining the presence or absence of a disorder.

The research reviewed supports the hypothesis that time of onset, dose, and duration of nutritional insults and interventions play critical roles in determining the nature and extent of any deficits (Morgane et al., 1993; Pollitt, 1996). What is not known is how much each of these three factors uniquely contributes to the eventual neurobehavioral outcome. Although there are no convincing animal models of psychopathology, animal studies designed to manipulate time of onset, dose, and duration of early malnutrition would help to explain the relative role of these components on neurochemistry, neuroanatomy, and some basic behavior (e.g., habit learning and recognition/spatial memory). Using neuroimaging and postmortem techniques, these findings could then be extended to human populations and, combined with evolving knowledge of the neurologic basis of psychopathology, may provide insight into the relationship between early malnutrition and the development of mental illness.

Overall, data indicate that specific micronutrient deficiencies can affect brain growth, cognitive development, and behavior. Nevertheless, adequate experiments explaining how deficits in these specific micronutrients result in the development of psychopathology (with the exception of mental retardation) have not been conducted. Examples of this approach include DNA microarray and proteomic and metabolomic assessments of targeted brain regions or processes (e.g., myelination, migration) following specific

timed nutrient deficiencies. The expectation would be to identify genes and gene products that mediate neuronal form and function. For example, studies investigating the hypothesized connection between prenatal folate deficiency, potential migration defects, and the later development of Schizophrenia could be addressed using such an approach. Studies of this kind are particularly important, given the significant number of individuals (in both developed and developing countries) affected by early micronutrient deficiencies, both apart from and in combination with generalized malnutrition.

Explaining how early malnutrition exerts negative effects on the developing nervous system is also a critical direction for future investigations. Possible neuropathogenic mechanisms of early malnutrition can be broken down into direct and indirect effects. Direct effects refer to those that are the primary result of malnutrition and are considered to underlie the subsequent pathology (e.g., disrupted neurotransmitter function, brain morphology, or myelination). These primary effects could potentially work through direct nutrient contact with DNA promotor regions (as seen with zinc) or at any other posttranscriptional regulatory sites. Indirect effects refer to effects that may potentiate other pathological processes or conditions associated with a pernicious outcome, for example, where the nutrient deficiency affects pregnancy integrity, maternal stress levels, or maternal parenting style. Other indirect effects could occur through nutrient deficiency effects on metabolism that in turn influence fetal programming of brain development. It should be noted that none of these mechanisms has been irrefutably linked to the development of psychopathology. They are merely presented here as possibilities to be considered; however, investigating all of these potential mechanisms would be fruitful grounds for future scientific inquiry.

Future research will need to take the knowledge gained at the regulatory level and apply it to physiologic studies at the systems level. For example, many studies have associated disturbances in various neurotransmitter systems (e.g., monoamergic and glutamatergic) with psychiatric disorders, including Schizophrenia, depression, and anxiety (Fishbein & Pease, 1994; Kaufman et al., 2000; Konradi & Heckers, 2003). Furthermore, evidence indicates that early malnutrition (or deficiencies in micronutrients such as iron) results in alterations in the development and eventual functioning of certain neurotransmitter systems (Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001; Manjarrez et al., 2003). Although it is difficult to speculate on a specific causative mechanism, prolonged increases in neurotransmitter concentrations yielding

diminished receptor density or augmented neurotransmitter uptake may significantly alter the neurochemical milieu affecting the functioning of the entire nervous system (Almeida et al., 1996; Wauben & Wainwright, 1999). Additionally, some have postulated that neurotransmitter systems interact with each other during development (Benes et al., 2000); thus, perturbations in one system due to malnutrition may affect the developmental course of other systems (Wauben & Wainwright, 1999). For example, researchers have conjectured that changes in the glutamate, GABA, and norepinephrine systems interact with and contribute to the dysregulation of the dopamine system observed in Schizophrenia (Friedman, Temporini, & Davis, 1999; Goldman-Rakic & Selemon, 1997; Laruelle, Kegeles, & Abi-Dargham, 2003; Syvalahti, 1994). In addition, dysregulation of certain neurotransmitter systems may adversely affect dendrite formation, gene expression, and neurophysiological functioning (Gietzen et al., 2004; Jousse et al., 2004; Ma et al., 2000; van Kesteren & Spencer, 2003).

The hypothesized relationship between malnutrition and hippocampal dysfunction and between hippocampal dysfunction and psychopathology suggest that this circuit plays a role in the emergence of psychopathology following early nutritional deficits. As highlighted previously, researchers have connected early deficits of protein/protein energy, iron, or zinc to hippocampal malformation/dysfunction (de Deungria et al., 2000; Jorgenson et al., 2003; Morgane et al., 2002; Schmidt et al., 2004; Tuormaa, 1995). This specific brain structure is noteworthy because it has been implicated in various types of psychopathology, including Schizophrenia, alcohol abuse, antisocial behavior, and anxiety/depression (E. S. Brown, Rush, & McEwen, 1999; DeBellis et al., 2000; Heckers et al., 1998; Heim & Nemeroff, 1999, 2001; Korbo, 1999; Korte, 2001; Laakso et al., 2000, 2001; Rajkowska, 2000). However, it is not known whether the hippocampus plays a direct causal role, if it modulates other structures involved in the pathogenesis of the disorder (e.g., frontal lobe structures), or if disruption in this region represents more generalized brain atrophy (Graham, Heim, Goodman, Miller, & Nemeroff, 1999). It is possible that, although affected, the hippocampus itself is not the crucial contributor to a deviant behavioral outcome. Rather, it is possible that hippocampal dysfunction disrupts projections to/from other brain structures, thus deranging the functioning of a wider cortical network.

Another effect of early nutritional deficits (specifically resulting from iron deficiency and essential fatty acid deficiency) is disrupted myelination (Kwik-Uribe et al., 2000; Roncagliolo et al., 1998). This is of note because researchers

have reported the occurrence of aberrant white matter structures in various psychiatric disorders (e.g., Schizophrenia and mood disorders; Cotter et al., 2001; Davis et al., 2003; Molnar, Potkin, Bunney, & Jones, 2003; Öngür, Drevets, & Price, 1998). Again, the relationship between the observed white matter abnormalities and the behavioral phenotypes of the disorder are currently unknown; however, they deserve future scrutiny because it is conceivable that the white matter changes are causally linked to psychopathology (Jones, 1997).

Maternal stress is an example of a more indirect effect that may partly explain the role of malnutrition in the emergence of mental disorders. For example, more than likely, chronic malnutrition rarely occurs in the absence of significant maternal stress (Gorman, 1995). Therefore, malnutrition could potentiate the effects of maternal stress or vice versa. The pervasiveness of maternal stress during the Second World War makes it unlikely that this factor alone can account for the pattern of deficits observed in the Dutch famine studies. Nevertheless, maternal stress cannot be ruled out as a factor contributing (either additively or synergistically) to these findings. Similarly, malnutrition of the child or infant likely occurs along with malnutrition of the mother. Thus, as suggested by the studies of Keys and colleagues (Franklin et al., 1948; Keys, 1946), significant malnutrition affects the psychological functioning of the mother and presumably her ensuing interactions with her child. Therefore, some of the consequences observed following malnutrition could partly result from disordered mother-child interactions. The magnitude of this effect—*independent of other environmental/biological influences*—remains unclear (Moffitt & Caspi, 2001). However, if the maternal behavior is severely abusive or pathological to the point of being unable to provide the minimal physical, perceptual, and social stimulation required for normal brain development, then a deviant outcome compounded by malnutrition is likely (Guesry, 1998; Jaffee, Caspi, Moffitt, & Taylor, 2004; Raine, Brennan, & Mednick, 1994, 1997; Stein & Susser, 1985; Tully, Arseneault, Caspi, Moffitt, & Morgan, 2004).

Some researchers have suggested that the early intrauterine environment “programs” the fetus early in gestation (Barker, 2001). This mechanism is regarded as an adaptive response helping the fetus to react during gestation to particular stressors such as malnutrition (Barker, 2001; Oliver et al., 1999; Seckl, 1998). Proponents of this theory argue that these adaptive changes become liabilities when the environmental challenge is no longer present (Barker, 2001; Oliver et al., 1999; Seckl, 1998). Barker and colleagues (Barker, Forsén, Uutela, Osmond, &

Eriksson, 2001) have invoked this fetal programming hypothesis to explain the relationship between retarded intrauterine growth and the later development of coronary heart disease. These researchers used the fetal programming hypothesis to explain their findings of a link between fetal undernutrition and the later development of depression (Thompson et al., 2001). Fetal programming in response to malnutrition could account for many of the descriptive findings regarding prenatal undernutrition; however, a precise mechanism for these alterations is still unknown (Seckl, 1998).

Another potential indirect effect connecting early malnutrition to the development of psychopathology is the decreased cognitive abilities observed in numerous studies. As discussed, research indicates that postnatal malnutrition can result in long-term reduction of intellectual abilities and cognitive skills (e.g., attention; Galler et al., 1986; Galler & Ramsey, 1987, 1989). These findings are important because intellectual ability measures obtained in middle childhood are highly stable into later life (Deary, Whalley, Lemmon, Crawford, & Starr, 2000; Deary, Whiteman, Starr, Whalley, & Fox, 2004). Other research indicates that low intelligence is an independent predictor of lifetime psychiatric contact in that lower intellectual capacity results in a significantly increased risk for developing psychiatric difficulties, including conduct problems and antisocial behavior (Moffitt, Gabrielli, Mednick, & Schulsinger, 1981; Walker, McConville, Hunter, Deary, & Whalley, 2002).

Jacobs and others (2002) found that although childhood cognitive ability and childhood psychopathology are predicted by independent genetic factors, a third genetic factor along with (unspecified) nonshared environmental factors predicts both. Thus, if postnatal malnutrition results in decreases in IQ sustained through middle childhood, these are likely permanent and may in turn lead to increased psychiatric contact. These results may be subtle and relatively small on the individual level. However, slight perturbations in the population IQ will greatly impact the number of individuals classified as mentally retarded and requiring social support services, thus increasing the financial cost to society (Tanner & Finn-Stevenson, 2002). Moreover, reductions in population IQ and specific cognitive skills (such as verbal reasoning) may increase the number of individuals requiring psychiatric support services and engaging in impulsive/delinquent behaviors (Arseneault, Moffitt, Caspi, Taylor, & Silva, 2000; Moffitt et al., 1981; Stevens, Kaplan, & Bauer, 2001; Stevens, Kaplan, & Hesselbrock, 2003).

Finally, early nutritional deficits may make an individual more vulnerable to insults (such as hypoxia) that are as-

sociated with the development of psychopathology (McNeil et al., 2000). Rao et al. (1999) provided some evidence for this hypothesis by showing that prenatally iron-deficient juvenile animals sustained more damage to the hippocampus following a hypoxic ischemic insult. Moreover, Fechner and colleagues (2001) showed that children admitted to hospital suffering from kwashiorkor exhibited decreased plasma antioxidant levels. Decreased antioxidant concentrations likely make these children more susceptible to neuronal damage/death after traumatic injuries such as anoxia or hypoxia-ischemia (Buonocore, Perrone, & Bracci, 2001; Zauner, Daugherty, Bullock, & Warner, 2002).

Similarly, compared to well-nourished children, malnourished children are more susceptible to cell damage and exhibit decreased DNA repair following an injury (Gonzalez et al., 2002). Gietzen and colleagues (1996) observed that rats with essential amino acid deficiencies displayed heightened seizure vulnerability. Research suggests that maternal zinc deficiency exacerbates the effects of prenatal alcohol exposure (Flynn et al., 1981).

These findings suggest that a nervous system already compromised by malnutrition is more vulnerable to additional insults such as toxin exposure or chronic stress. As discussed in the section on neurobiology, there is a potential for malnutrition or any early insult to alter the fundamental organization or structure of the developing brain. Although these modifications may prove beneficial in the short term (e.g., by conserving energy or reallocating resources), they may prove detrimental in the long term, possibly by decreasing behavioral and/or cellular plasticity (Barker, 2001).

Thus, malnutrition may serve as a catalyst disrupting normal development, but it may not have an enduring effect unless occurring proximally with another insult. Furthermore, the consequences of early malnutrition may not be revealed until a future stressor tries the plasticity of the system. This model is analogous to the diathesis-stress theory of mental disorders. In this model, undernutrition could be the stress (second injury), and the diathesis (initial damage) could stem from a genetic vulnerability or from other, already present environmental risk factors. Conversely, early malnutrition and its effects could be present first, so that a later infection, toxin exposure, or hypoxic/ischemic event would tip the scales toward an undesirable outcome. As discussed in the introduction, another variable to consider in this system is an individual's ability to maintain homeostasis in response to a challenge. This model may explain some of the discrepant findings in the literature. That is, it posits that each individual has his or her own threshold of how much damage via malnutrition

(or other environmental insults) he or she can endure before exhibiting an aberrant phenotype. It also hypothesizes that malnutrition exerts its maximal effect if it occurs in the context of an already compromised system. Again, this is merely a hypothesis and it should be rigorously tested (including the formulation of models that strive to describe this threshold in terms of numerical relationships and which factors are the best predictors of eventual outcome).

The question is not whether severe malnutrition (i.e., starvation) leads to adverse outcomes, because it is obvious that beyond a certain threshold of caloric restriction, conception becomes unlikely, miscarriage is inevitable, and death eventually results if adequate energy intake is not restored (Coad, Al-Rasasi, & Morgan, 2002; King, 2003; Stein et al., 1972). Rather, the question that future research should address is: Given a limited supply of energy, protein, or specific micronutrients, is an individual at an increased risk for developing psychopathology? Complicating the picture, available research suggests that generalized malnutrition rarely exists without micronutrient (iron/zinc) deficits, decreased parental intellectual abilities, deficient psychosocial stimulation, chronic childhood illness, or unsanitary living conditions (Guesry, 1998; Ivanovic et al., 2002; Pollitt, 1969; Stein & Susser, 1985). Even in the case of the Dutch hunger winter, the population was not free from significant wartime- and famine-induced stress. Therefore, it is difficult to discern if there is a unique contribution of early malnutrition to the development of psychopathology, and what, if any, is the relationship between malnutrition and other risk factors (i.e., mediational, additive, or synergistic).

Early malnutrition appears to be a topic very well suited to a multidisciplinary approach that includes basic science (neurobiology and biochemistry) as the foundation, translational research (such as using animals to model various paradigms of malnutrition), and finally comprehensive human investigations which include measures of motor, perceptual, cognitive, and intellectual abilities as well as objective measures of personality and psychopathological symptoms. These human studies should also endeavor to match participants or otherwise statistically control for potential confounds such as SES, parental education/IQ, familial history of mental illness, toxin exposure, and living circumstances. Although costly and difficult to conduct, a human study incorporating all of these components would provide valuable data that would greatly augment our understanding of the long-term effects of early malnutrition and specify how this condition interacts with other risk factors.

The potential for interactions may explain the relative effectiveness of nutritional intervention programs in

developing countries compared to the often modest benefits shown by similar endeavors in countries such as the United States (Pollitt, 1996). That is, in developing countries, the population is likely to be chronically undernourished but may not exhibit elevated rates of psychopathology, and parents might provide a stable home environment. Conversely, in developed countries, individuals at risk for early malnutrition are more likely to have genetic and additional environmental risk factors, increasing their chance of expressing a deviant phenotype. This is merely a speculation and is not intended to minimize the potential impact of early malnutrition or the need to address this issue, but rather to emphasize the idea that many malnourished children (especially in developed countries) possess other substantial risk factors such as poverty, unstable home environments, deficient psychosocial stimulation, and genetic propensities, which may complicate intervention efforts. Again, designing efficient, beneficial interventions is another area that future studies should explore. Implementing successful interventions in countries such as the United States will likely entail carefully designed, targeted procedures (such as ensuring proper prenatal care and nutrition, encouraging breast feeding and parental involvement, better parental and childhood nutrition education, proper vaccinations and postnatal nutrition) that begin early and aim to treat the gestalt of the circumstances and not merely a single destructive component of the milieu (Ramey & Ramey, 1998).

Cognitive neuroscience was formalized as a scientific area of inquiry in the late 1970s, when scholars from various disciplines sought to bring together their investigations of how brain processes enabled mental functions (Gazzaniga, Ivry, & Mangun, 2002). Less formally, the field began quite a bit earlier, when Franz Joseph Gall introduced his concept of phrenology, the notion that the brain is organized around a group of cognitive tasks, each of which has a hypothesized basis in brain function. Gall proposed that when the function was frequently implemented, its corresponding brain area increased in size, causing a bump to protrude from the skull. He believed that a careful analysis of the skull's surface could reveal characteristics of an individual's personality and intellect (Gall & Spurzheim, 1810; Spurzheim, 1825). This theory

was rejected by Gall's contemporaries (Flourens, 1824), but the general goal of localizing cognitive and other behavioral functions within the brain was pursued by early experimental neuropsychologists, such as John Hughlings Jackson, in the mid-1800s (Taylor, 1958).

When Santiago Ramon y Cajal (1906/1967) used the newly developed Golgi (1906) stain to identify neurons as unitary entities that transmitted electrical impulses in a unidirectional fashion, studies of brain structure-function relations proliferated. Neuroscientific pioneers relied on lesion studies in animals and humans to craft theories of brain-behavior relations. Among these were David Hubel and Torsten Wiesel, who recorded activity from single neurons in the visual cortex of cats and demonstrated that they responded reliably to discrete forms of experiential

stimulation, provoking a host of questions regarding the dynamics of experience, neurobiology, and their interactions (Hubel & Wiesel, 1962, 1965). Angelo Mosso, an Italian physiologist who studied skull defects, anticipated the development of neuroimaging when he observed an association in his patients between cerebral blood flow and increases in neuronal activity (cited in Raichle, 1998). Based on Mosso's observations in the years following World War II, scientists began to measure blood flow in the brains of laboratory animals. David Ingvar and Neils Lassen were the first to devise a method for the measurement of changes in metabolism and cerebral blood flow during cognitive performance (Raichle, 1998), a technique that gave way to positron emission tomography (PET), which was developed at Washington University in St. Louis. The successful measurement of hydrogen atoms in a magnetic field prompted the development of the first magnetic resonance imaging (MRI) scanners, and most recently, a method of tracking blood flow using MRI made functional magnetic resonance imaging (fMRI) possible (Gazzaniga et al., 2002; Raichle, 1998). Functional MRI measures and localizes activity in the behaving human brain. From a methodological standpoint, cognitive neuroscience has proliferated at an exponential rate, so that we are now able to view the dynamics of brain activity in individuals across the life span as they perform behavioral tasks.

The ability to view the living brain in action permits examination of how such activity changes or is altered in response to experiences, including illness, pharmacological treatment, and normal aging processes. In the context of the heated philosophical debates regarding nature and nurture that have motivated psychological inquiry since the field's inception, it has been natural to apply questions regarding brain-behavior relations to the study of child development. With the advent of electrophysiological recording, MRI, and fMRI, almost every conceivable cognitive function has been considered from a human developmental neuroscientific standpoint, including language development (Bates, Vicari, & Trauner, 1999; Merzenich et al., 1996), visual perception (Maurer & Lewis, 2001), face recognition (de Haan & Nelson, 1997), learning and memory (Nelson, 1995; Pascalis & Bachevalier, 1999), and attention (Johnson, 1990; Richards, 2000).

With these substantial advances in cognitive neuroscience and increased knowledge regarding postnatal brain development, there has been an escalating interest among scientists in the emergence of higher-order cognitive processes and their neural substrates. These processes include planning, foresight, and goal-directed behaviors that

require integration across time and space (working memory), inhibitory control, and flexibility in selecting appropriate responses. Current theories suggest that each of these behaviors is controlled by a distributed information-processing network, orchestrated within dorsal and/or ventral regions of the prefrontal cortex (PFC). For instance, working memory and inhibitory control have been associated with dorsolateral PFC activity, and the use of these skills to pursue future goals under highly salient emotional conditions recruits the ventromedial PFC. PFC abnormalities have been noted in a number of clinical conditions such as substance abuse (associated with aberrant ventromedial PFC function) and Schizophrenia (associated with dorsolateral PFC dysfunction).

In this chapter, I consider how psychopathology can develop as a consequence of deficiencies in the PFC's ability to regulate behavior, highlighting how cognitive neuroscientific techniques have contributed to this area of inquiry. To put this discussion in context, I first briefly define what is meant by the *prefrontal cortex*. Historical perspectives on prefrontal function as derived from early studies in experimental neuropsychology are shared, followed by a discussion of behaviors that are believed to be PFC-mediated. How these behaviors develop from infancy through young adulthood is discussed next. The discussion of behavioral development emphasizes how cognitive neuroscientific techniques have been used to study the correspondences among the PFC's structural, neurophysiological, and functional developments. Once these normative principles of PFC development have been derived, their implications for psychopathology in the developmental period are considered.

THE PREFRONTAL CORTEX DEFINED

In the primate, the *frontal cortex* has been defined on anatomical and cytoarchitectural grounds. Anatomically, its posterior border is the central sulcus, a fissure that cuts across the brain's lateral surface, extending medially to separate the parietal lobe from the more anterior frontal cortex. On the inferior side, the frontal lobe is separated from the temporal lobe by the lateral fissure. Just anterior to the central sulcus is the precentral gyrus (also referred to as the primary motor cortex: Brodmann's area 4; see Figure 7.1: Pandya & Yeterian, 1990). Secondary motor areas, including the premotor cortex, frontal eye fields, supplemental motor area, and Broca's area (Brodmann's areas 6, 8, and 44) lie anterior to, and slightly beneath, the primary motor cortex. The terms *frontal cortex* and

Figure 7.1 Based on cytoarchitectural characteristics, Brodmann created this anatomical map of the primate brain, including the prefrontal cortex. Each region was defined based on the presence of distinctive cellular features. *Source:* Reprinted from “Prefrontal Cortex in Relation to Other Cortical Areas in Rhesus Monkey: Architecture and Connections,” by D. N. Pandya and E. H. Yeterian, 1990, *Progress in Brain Research*, 85, pp. 63–94. With permission from Elsevier.

prefrontal cortex are not synonymous. The prefrontal cortex, an expanse of tissue that constitutes about half of the human frontal cortex, describes all portions of the frontal lobe that lie anterior to these primary and secondary motor regions. Through the use of anatomical tracing techniques, the prefrontal cortex has also been defined as the projection field of the dorsomedial thalamus (Goldman-Rakic & Porrino, 1985; Rose & Woolsey, 1948; Walker, 1940). Several subdivisions of the PFC are currently recognized, including the *lateral* (lateral aspects of areas 9 to 12, 45 to 46, and the superior portion of area 47), *ventromedial* (the medial aspects of areas 9 to 12 and inferior portion of area 47), and *anterior cingulate* (areas 24, 25, and 32) cortices.

In the mature primate (including the human), the prefrontal cortex is reciprocally connected, within and between each brain hemisphere, with various cortical and subcortical structures, including the superior temporal cortex, posterior parietal cortex, posterior cingulate gyrus, thalamus, limbic system, and caudate nucleus (Cavada & Goldman-Rakic, 1989; Selemon & Goldman-Rakic, 1988). On the basis of its extensive connectivity with the rest of the brain, the PFC is in a unique position to coordinate processing among these regions so that the entire brain can function as an integrated and well-regulated unit.

HISTORICAL PERSPECTIVES ON THE PREFRONTAL CORTEX AND BEHAVIORAL REGULATION

The cognitive neuroscientific investigation of the prefrontal cortex began more than 150 years ago with a dramatic case study. In the summer of 1848, Phineas Gage was a 25-year-old construction foreman employed by the Rutland and Burlington Railroad in the state of Vermont. Known by his superiors as a highly efficient and capable man, he was assigned the difficult task of supervising a group whose mission it was to lay down new tracks for the railroad's expansion across the United States. On one fateful afternoon, Gage was preparing detonations, which required a hole to be drilled into a section of rock. The hole was then filled halfway with explosive powder, a fuse was inserted, and the powder was covered with sand. The sand had to be gently packed in with the use of an iron rod, after which the fuse was lit. Gage was momentarily distracted as he performed this sequence and reportedly began to tap the explosive powder before he had covered it with sand. A fire ignited, and the iron rod, weighing 13.5 pounds and measuring over an inch in diameter, blew upward into Gage's face (Damasio, 1994). The rod entered his left cheek, crossed the frontal region of his brain, and exited through the top of his head, landing several hundred feet away. Gage was knocked to the ground but, remarkably, was awake and communicative (Damasio, 1994; Jasper, 1995). He was cared for by John M. Harlow (1868), a local physician, who described the case in a letter written to the *New England Journal of Medicine*. Not only was it notable that Gage survived this terrible accident, living for another 15 years, but Harlow's description of Gage's change in personality was among the first scientific writings to emphasize the importance of the frontal lobe in the mediation of behavioral control.

As a consequence of the injury, Harlow commented that the “balance” between Gage’s intellect and his “animal propensities” seemed to have been destroyed. Gage was described as profane, irreverent, and capricious. His friends commented that he was no longer himself. Having made a dramatic physical recovery, Gage was nonetheless eventually discharged from his leadership position due to his unpredictable behavior. He held a series of menial jobs, each of which he retained for only a short period. For a time, he became a circus attraction at Barnum’s Museum in New York City. He eventually died in 1861 following a brief illness that was accompanied by grand mal seizures.

Gage’s case provides an example of how a lesion to the ventromedial PFC led to behavioral *release* or disinhibition. His story remains remarkable in conveying two major points to the scientific community: first, that social behavior and individual differences in personality style can be dissociated from general intellect, and second, that aspects of an individual’s personality might have a biological (brain) basis.

Around the same period of time, Paul Broca, a French neurologist, treated a stroke victim who was left with the ability to understand language, although he could not speak (Berker, Berker, & Smith, 1986). After the patient’s death, it was discovered that the area of the brain that was damaged was localized to the left anterior portion of the frontal lobe, which came to be called *Broca’s area*. Soon afterward, in 1876, it was demonstrated by Carl Wernicke (1908) that damage to the temporal-parietal junction, also on the left side, rendered one able to speak but unable to understand language. Together, these findings were monumental, suggesting a dissociation between discrete aspects of language and specific structures within the brain’s left hemisphere.

Human case studies such as these led neuroanatomists such as Brodmann (Figure 7.1) to focus on mapping cytoarchitectural features of the cerebral cortex. These cases also inspired scientists to derive animal models of brain-behavior relations. Early animal models relied on the use of experimental focal lesions and the innovative technique of implanting electrodes into the brains of behaving animals (e.g., Hubel & Wiesel, 1962, 1965).

Carlyle Jacobsen (1935) used the lesion technique to examine the effects of bilateral frontal lobe removals on a range of cognitive functions in adult monkeys and chimpanzees. After recovery from surgery, Jacobsen’s animals were physically intact, with no apparent sensory or movement difficulties. They were able to perform visual and auditory discriminations and to recall the spatial orientations

of objects under immediate response conditions. However, if a delay was introduced between the presentation of a stimulus and the required response, the animals were impaired in their performance. Tasks that impose such delays are referred to as *delayed response tasks*. In the classic variant of the delayed response (DR) task (Hunter, 1913), a research subject (animal or human) is presented with two identical food wells, one of which is baited within full view with a desired object and then occluded. Following a delay interval, typically in the range of a few seconds, the subject is permitted to retrieve the object from the remembered location without the benefit of recognition memory. Although the task is very simple, it has been described over the years as a microcosm of future-directed behavior, because one must represent, through mentation, a future action that is necessary for goal attainment. That is, at the time that the desired object is hidden, one formulates a representation of that object, its motivational value, and where it can be retrieved. The nature of the action that will permit retrieval (e.g., what to do and where to do it) presumably also becomes part of the representational structure that is held in mind until that action can be executed.

Following Jacobsen’s landmark finding, DR tasks became preferred means of examining the integrity of frontal lobe function in laboratory animals and, to a lesser extent, in humans with suspected frontal lobe damage. Indeed, one of the most consistently employed measures of prefrontal function has been the *spatial* DR task, where the information to be remembered concerns the desired object’s location.

In addition to recent memory deficits, Jacobsen’s lesioned animals demonstrated other difficulties, including loss of initiative, lethargy, and distractibility (reviewed by Jasper, 1995). In contrast to the disinhibition displayed by Phineas Gage, the disturbances experienced by these animals illustrate how PFC lesions can result in a seemingly opposite pattern of behavioral dysregulation, one that involves loss of function. Another notable finding in Jacobsen’s monkeys was that individual animals’ personality traits were *differentially* altered by the frontal lesions. For instance, one animal that was noted to be particularly unmanageable prior to surgery became complacent and seemingly happy afterward. The Second World Congress of Neurology in 1935 featured this work, as well as a presentation by Walter Penfield from the Montreal Neurological Institute. Penfield presented the results of a series of case studies in which patients underwent frontal lobe excisions for the treatment of brain tumors. Penfield noted that although these individuals retained a great deal of insight,

introspection, and ability to follow instructions after recovery, they seemed unable to perform planned actions (Jasper, 1995; Penfield & Evans, 1935).

At one point during the meeting, according to Jasper (1995), a well-known Portuguese neurologist, Antonio Egas Moniz, asked why, if frontal lobe excisions eliminated aggressive behavior in animals, it would not be feasible to use similar surgical techniques to alleviate anxiety and frustration in humans. Upon his return to Portugal, Moniz, who coined the term *psychosurgery* (cited by Jasper, 1995), developed procedures for human frontal leucotomy (or lobotomy; both terms refer to the surgical interruption of fiber tracts that link the prefrontal cortex with other brain regions). Walter Freedman brought the practice to the United States, performing the first prefrontal leucotomy on a patient with depression in 1936. The technique was reportedly successful in regulating the behavior of difficult-to-manage cases of mental disorder and was also adopted by many well-reputed neurological institutes, including the Montreal Neurological Institute, where Penfield was approached by many patients requesting the procedure to relieve them of chronic emotional distress (Jasper, 1995). Penfield is best known for his work with intractable epilepsy (Penfield & Jasper, 1954), and the Institute's scientists became renowned for their descriptions of pre- versus postoperative behavior in humans who received lobotomies as treatments for frontal lobe epilepsy. Furthermore, Moniz won the Nobel Prize in 1949 for the use of frontal lobotomies for the treatment of mental disorders.

Prefrontal lobotomies were performed on thousands of patients in the 1930s and 1940s. When the procedure was finally subjected to increased scientific scrutiny, it was concluded that although there were a limited number of beneficial effects in extreme cases, outcomes were generally poor. The practice seems barbaric by current standards, but it must be emphasized that few treatment options were available to patients during this time period. With the advent of psychopharmacological advances in the 1960s, lobotomies became increasingly obsolete. And although the end does not necessarily justify the means, this era of prefrontal lobotomy called attention to the importance of the prefrontal cortex in the maintenance of high-level cognition and behavioral regulation. Together with findings from individual case studies, the lobotomy illustrated to the scientific community that PFC lesions could result in either behavioral excesses (disinhibition) or shortfalls (anhedonia). These paradoxical findings can be integrated by understanding that a critical function of the PFC may be to maintain behavior in a flexible but adaptive equilibrium.

It was the practice at the Montreal Neurological Institute in the 1950s and 1960s for patients undergoing frontal excisions for the treatment of epilepsy to complete comprehensive cognitive testing using standardized as well as newly developed measures. This innovative work led to reports on a number of classic neuropsychological cases and generated several influential theories regarding PFC function (Milner, 1995).

For example, Penfield's epilepsy work was notable for the case of K.M., who in 1928 at the age of 16, was struck by an overhead feeder while working in a sawmill (Milner, 1995). He sustained a penetrating injury to both frontal lobes and was comatose for more than a week. He developed severe major epileptic seizures after the injury, and like Phineas Gage, his behavior between seizures was described as irresponsible and childish. In 1938, Penfield removed an extensive area of scar tissue involving the anterior third of both of K.M.'s frontal lobes, which led to improvement in the patient's seizures as well as increased behavioral control. Brenda Milner, one of the Institute's neuropsychologists, conducted a follow-up study of K.M. in 1962, when the patient was 48 years old. She replicated earlier findings that even without a substantial portion of his prefrontal cortex, K.M. had an overall IQ in the average range, which would seem to represent a very positive outcome. However, using the newly developed Wisconsin Card Sort Task (D. A. Grant & Berg, 1948; Milner, 1963) to measure K.M.'s reasoning skills, Milner demonstrated that his performance was severely impaired. The Wisconsin Card Sort, now a classic means of assessing prefrontal function in clinical and experimental settings, presents an individual with four cards (see Figure 7.2). Each card varies on three stimulus dimensions: color, shape, and number (e.g., one card might consist of one yellow star and another might consist of four blue squares). The task is to sort additional cards on the "correct" dimension, based on feedback from an experimenter. Thus, one might start the task by sorting cards according to the color of the items on the card. After each response, the test taker is told that he or she is correct (or not). After 10 consecutively correct responses, the correct sorting criterion is changed, and the test taker must shift his or her responses, based on trial-and-error feedback, to one of the other possible dimensions. In theory, the three possible sorting dimensions have to be held simultaneously in mind to execute these behavioral shifts. Frontal lobe-lesioned patients tend to perseverate in their response sets, applying the first-learned sorting rule repeatedly, even when they are told that it is no longer correct. Milner's (1995) use of the task on a number of patients with frontal lesions, as compared to those with lesions in posterior or

Figure 7.2 Schematic illustration of the Wisconsin Card Sort Task (Milner, 1963), one of the classic measures of prefrontal function. Individuals are presented with four display cards that vary on three dimensions: shape of the presented stimulus, stimulus color (depicted here as different patterning of stimuli), and the number of stimuli on each card. A deck of cards is also provided, and individuals must sort each card based on one of the three possible dimensions. The experimenter reinforces each sort by telling the participant that he or she is either correct or incorrect. Thus, the task requires an individual to utilize feedback to guide each response and to shift between each of the three possible sorting dimensions.

temporal regions, led her to conclude that although frontal lobe patients are appropriately responsive to environmental stimuli, they appear to have difficulty using such stimuli as cues in regulating their actions.

An alternative explanation suggested by Luria (1966) was that the dysregulated behavior of patients with frontal lobe injuries was due to an inability to verbally guide behavior. Luria's formulation was very influential, with obvious implications for understanding prefrontal development, as very young children are deficient in expressive language skills. However, his view is thought by some (i.e., Milner, 1995) to be too narrow, because frontal lobe-damaged patients exhibit difficulties on nonverbal tasks, such as stylus maze learning (Corkin, 1965; Milner, 1965), nonverbal design fluency (Jones-Gotman & Milner, 1977), spatial delayed response (Jacobsen, Wolfe, & Jackson, 1935), spatial delayed alternation (Jacobsen & Nissen, 1937), recency memory (Konorski, 1959; Milner, Corsi, & Leonard, 1991), and the temporal organization of memory (Petrides & Milner, 1982).

To summarize, although the work conducted in Montreal and elsewhere was primarily behavioral in nature, derived from a combination of animal and human clinical models that might seem primitive given today's technical advances,

it cannot be overemphasized in its importance. It represents the foundation on which the neuroscience of higher-order cognition has been built.

THE DEVELOPMENTAL COGNITIVE NEUROSCIENCE OF PREFRONTAL FUNCTION

Over the past 40 years, emphasis on single structure/single function explanations of higher-order cognition have been replaced by more contemporary views of information processing that emphasize the manner in which mentation is achieved through networks of interconnected regions (Goldman-Rakic, 1988; Mesulam, 1998). This view has provoked interest in how it is that various brain regions are able to communicate with one another and how this communication might be disrupted in psychological (as opposed to neurological) disorders. The application of cognitive neuroscientific techniques to psychopathology has also encouraged investigations of cognition-emotion interactions, how these interactions promote regulated behavior, and how they are achieved at the neural level. We know that neurochemicals form the basis of neural communication, and thus, the neurochemistry of behavioral regulation has become an area of great interest, reinforced by a desire to understand, at the cellular and network levels, the mechanisms through which psychopharmacological treatments facilitate recovery from emotional disorders. These endeavors, together with theories of psychopathology that emphasize neurodevelopmental mechanisms (Cicchetti & Walker, 2003; Weinberger, 1987), have sparked interest in how the development of the prefrontal cortex might differ from that of other brain regions and how individual differences in prefrontal development might confer vulnerability to psychopathology.

Sources of Individual Variation in Prefrontal Cortex Structure

Sources of potential variation in PFC structure and function begin at the point of conception and extend throughout the human life span. The structural development of the PFC begins prenatally. Following conception, the human embryo develops from three cellular layers: an outer ectoderm, an inner endoderm, and an intermediate mesoderm. These layers give rise to, respectively, (1) the nervous system, lenses of the eyes, outer skin, hair, and inner ear; (2) the digestive organs; and (3) the skeletal system and voluntary muscle system. Thus, the nervous system arises initially from the ectoderm layer, which comes to surround the other two layers. Its formation begins 2 to 3 weeks after conception and can be observed when the dorsal surface of

the embryo begins to thicken. This thickening gives rise to the neural tube, a primitive structure that will eventually develop into the brain and spinal cord. By the 7th week of gestation, the cerebral hemispheres encompassing the brain's neocortex are visible (Spreen, Risser, & Edgell, 1995). The cellular events that lead to cortical development have not been adequately described in the human fetus due to methodological limitations, but they have been extensively examined in the nonhuman primate. It is generally assumed that a comparable sequence of events occurs in both species (Goldman-Rakic, Bourgeois, & Rakic, 1997).

Neurogenesis and Cellular Migration

Cortical development begins when mitosis promotes the generation of cells in the *ventricular zone* of the neural tube. This region develops adjacent to the ventricles of the brain. The initial *precursor* (or stem) cells, once formed, are undifferentiated. Mitosis acts on them to produce two cell lines: neuroblasts (nerve cells) and glioblasts (glial cells; Spreen et al., 1995). Using [³H]thymidine, a unique autoradiographic labeling compound, it has become possible for neuroscientists to evaluate the time course of neurogenesis during the pre- and perinatal periods in nonhuman primates. This line of research, largely directed by Pasko Rakic and his colleagues at Yale University, has revealed that neurons destined for both posterior (visual) and prefrontal association cortical regions develop between embryonic day 40 (E40) and embryonic day 100 (E100) in the rhesus macaque (Rakic, 1974, 1995). After E100 (corresponding to the second trimester of human gestation), no additional formation of neurons destined for the neocortex has been observed (Rakic, 1985).

When this generative phase of neuron formation is completed, the neuroblasts move from the proliferative zone of the neural tube toward their permanent locations, a process referred to as *migration*. Proliferation and migration ensue in parallel for some time, during which an intermediate zone forms between the ventricular zone of the neural tube and the area that has been the target of developing cells (referred to as the marginal zone). By 8 to 10 weeks after conception, this intermediate zone forms the cortical plate and an underlying subplate, a secondary and transiently present locus of continued cell proliferation as well as a holding area for incoming projections from subcortical regions (Kostovic & Rakic, 1990; Rakic, 1977, 1995). In the primate, the subplate zone in the frontal cortex is as much as four times wider than what has been observed in other cortical areas, most notably the occipital cortex (Rakic, 1995). Rakic (1995) speculates that

the wider subplate is necessary to accommodate the relatively greater number of afferent fibers that form between other cortical regions and the developing frontal cortex (Kostovic & Rakic, 1990). Typically, the subplate degenerates with continued development, leaving only subtle vestiges scattered throughout the white matter of the adult cerebral hemispheres (Rakic, 1995).

As neurons continue to migrate between the 11th and 15th weeks of gestation, the cortical plate gradually forms the brain's six-layered neocortex. To achieve this laminar pattern, migration progresses in an inside-out fashion. That is, the initial layer to form within the cortical plate is the deepest (sixth) cortical layer, and the last, most superficial, layer forms when cells have migrated over relatively long distances through the five deeper layers. The cells, dependent on voltage-gated ion channels and receptors for N-methyl-D-aspartate (NMDA), are believed to use the fiber shafts of radial glial cells as scaffolds to negotiate these distances (Rakic, 1995).

This general sequence characterizes all regions of the developing cortex, including the prefrontal cortex. However, Rakic (1995) emphasizes that the migratory pathway that must be traversed by developing neurons is particularly extensive in the primate's frontal lobe. The need for cells to correctly negotiate such distances may increase the likelihood of migratory errors in the PFC. When cells root themselves in nonoptimal locations, the pattern of synaptic connectivity that results is disruptive to information processing, a process that has been hypothesized to contribute to the deficits observed in several congenital conditions, including Fetal Alcohol Syndrome (Jones & Smith, 1973, 1975), and one that has been theorized to underlie symptoms of thought disorder in Schizophrenia (Akbarian et al., 1993). Thus, accurate migration is critical for the cytoarchitectural formation of the cortex and profoundly influences its later function. Once migration is accomplished, the aggregation of cell types within each cortical layer promotes regional specialization and differentiation.

Synaptogenesis

Differentiation involves a number of processes in addition to the formation of cell bodies, including selective cell death, the growth of axons, the sprouting of dendritic processes, and the formation of functional synaptic connections (Spreen et al., 1995). The establishment of functional synaptic connections represents a significant milestone in the course of neural development, because it indicates that behavior can be guided by cortical neurons. The synaptic

development of the prefrontal cortex has been studied most extensively in the nonhuman primate (Goldman-Rakic et al., 1997) and in a more limited fashion through human autopsy data (Huttenlocher, 1979).

In the rhesus macaque, the typical gestation period lasts for 165 days (~5.5 months), and the presence of the first synapses is evident 3 months prior to birth (Bourgeois, Goldman-Rakic, & Rakic, 1994). At midgestation, corticocortical and thalamocortical afferents permeate the cortical plate, and there is an overproduction of synaptic connections on the dendritic spines of pyramidal cells. (Dendrites are the postsynaptic arborizations emanating from the cell body that receive input from other cells via junctions referred to as synapses. Axons, in turn, are fibers that presynaptically propagate electrical signals to synaptic junctions. Dendrites themselves have extensions—spines—that contain synaptic contact points.) At the time of birth, the adult pattern of sulci and gyri is generally present on the surfaces of the macaque (Goldman & Galkin, 1978) and human (Spreen et al., 1995) brains. This is the time point when the maximal accumulation of synapses in the PFC occurs (Bourgeois et al., 1994) and the time point when the majority of corticocortical and thalamocortical afferents intersect the cortical plate (Schwartz & Goldman-Rakic, 1991). Spine formation continues until 30 to 60 contacts per 100 μm^3 of neural tissue have formed, approximately 2 months after birth, at which time a plateau is reached. This plateau, representing synaptic density at higher-than-adult levels, is maintained throughout childhood until the onset of puberty (Bourgeois et al., 1994; Goldman-Rakic et al., 1997).

This overabundance of synapses is thought to ensure a high degree of redundancy (and hence, malleability), as multiple avenues might exist between neurons to subserve the same behavioral process. Imagine a series of highways and side roads that connect one major city to the next. To travel the distance between the two, one route might be maximally advantageous or efficient, but others are available in the event that the preferred one is impeded. These secondary routes can be used provided that they are maintained and reasonably well-traveled. Analogously, early to middle childhood would seem, on a synaptic level, to represent a time of great possibility, particularly if experience (environmental enrichment or stimulation) serves to facilitate synaptogenesis, creating multiple avenues of communication between distal brain regions. This time period might also represent a time of decreased vulnerability to injury. If the “preferred” avenue connecting distal regions

is damaged, others remain available and could be strengthened with use.

Synaptic Pruning

In the 3rd year of monkey life, corresponding to the period of adolescence/young adulthood in the human, a slow and steady decline in the number of synapses occurs. Synaptic attrition or pruning does not seem to occur in a random or haphazard way, but is a process that appears to be specific to asymmetric synaptic junctions (Goldman-Rakic et al., 1997; Rakic, 1995). Asymmetric synapses regulate excitatory transmitters, such as glutamate. The other type of junction, the symmetric synapse, regulates GABA, the major monoamines, and neuropeptides, all of which have local inhibitory functions. Symmetric synapses, once formed early in life, do not appear to change over the course of neural development or the ensuing life span (Bourgeois et al., 1994; Bourgeois & Rakic, 1993; Rakic, Bourgeois, Eckenhoff, Zecevic, & Goldman-Rakic, 1986). This change in the ratio of asymmetric to symmetric junctions alters the balance between excitatory and inhibitory neurotransmission. Pruning continues at a slight but measurable and steady rate for the remainder of the primate (macaque) life span. Huttenlocher and Dabholkar (1997) favor the view that experience has the effect of incorporating existing synapses into functional circuits and that unused synapses disappear, a process referred to as functional stabilization (Changeaux & Danchin, 1976).

Is the Prefrontal Cortex Different from Other Regions in Its Synaptic Development?

Whether or not synaptogenesis and synaptic elimination are relatively prolonged processes in the frontal cortex versus other cortical regions has been a matter of debate based on consideration of animal versus human data (Huttenlocher & Dabholkar, 1997; Rakic, 1995). It has traditionally been thought that the brain develops according to a hierarchical temporal sequence, with phylogenetically older regions maturing earlier than newer regions. Accordingly, brain development would proceed in a caudal-to-rostral sequence, with sensory areas developing prior to motor regions, and motor regions developing prior to association regions, including the prefrontal cortex. This maturational gradient would presumably be reflected equivalently in relation to all aspects of neural development, including neurogenesis, synaptogenesis, and myelination. Moreover, with respect to synaptogenesis, one expectation has been to observe concordance between a region's synaptic development and the functional maturation of behaviors subserved by that region. For instance, in the primary visual cortex,

synaptogenesis rapidly increases during the first few months of human life, and this time of maximum synaptic density coincides with the development of stereoscopic vision (Huttenlocher & deCourten, 1987; Huttenlocher, deCourten, Garey, & Van Der Loos, 1982). To examine whether there is a similar concordance between synaptic density and behavioral development in the frontal cortex, Huttenlocher and Dabholkar compared the autopsied brains of fetuses, young children, and adults. Based on a quantification of synaptic density in selected brain areas, they concluded that there was a protracted course of synaptic development in the frontal lobe as compared to posterior regions, notably the primary auditory cortex in the superior temporal lobe. This finding appeared to make intuitive sense in light of the fact that the behavioral development of functions attributed to the frontal lobe also appeared to follow a sequential hierarchical course, appearing late in the 1st year of human life and reaching functional maturity many years later (as described later in the chapter).

In contrast to Huttenlocher's findings, data from nonhuman primates suggests that there is concurrent production of synapses across cortical regions (Rakic et al., 1986). Rakic and colleagues examined numerous areas of the neocortex in the brains of individual monkeys, including the prefrontal, primary visual, cingulate, motor, and somatosensory cortices, and found that the production of synapses occurs at a similar rate in all regions examined (Goldman-Rakic et al., 1997). The decline in synaptic density also appears to occur contemporaneously in these regions (Rakic et al., 1986).

These findings are difficult to reconcile. On the one hand, Rakic and colleagues have made a compelling argument in favor of their approach and general conclusions. They argue that methodological confounds may account for the apparent discrepancy between the monkey and human data (Goldman-Rakic et al., 1997; Rakic, Bourgeois, & Goldman-Rakic, 1994). On the other hand, Huttenlocher's findings are intuitively appealing and better approximate the apparent time course of the PFC's behavioral maturation in humans.

Metabolism

PET has also been used to examine brain metabolism from infancy through adolescence and into adulthood. Chugani (1998) reported changes in resting glucose metabolism from infancy to young adulthood. Newborns exhibit their highest levels of metabolism in sensory and motor regions, as well as in the hippocampus, thalamus, and brainstem. By 2 to 3 months of age, the metabolic rate

increases in primary sensory regions of the parietal and temporal cortices and in the primary motor cortex. It is also evident from monkey studies that concentrations of the major monoamine neurotransmitters, including dopamine, norepinephrine, and serotonin, rapidly increase from 2 to 5 months of postnatal life (Goldman-Rakic et al., 1997; Goldman-Rakic & Brown, 1982), as do corresponding transmitter receptor sites (Lidow & Rakic, 1992). Between 6 and 12 months of age, glucose metabolism increases in the human frontal cortex. Thus, these data seem to reinforce the notion that association areas lag behind primary sensory and motor regions in their functional development.

On a more general level and consistent with the suspected pattern of synaptogenesis in the primate brain, Chugani (1998) found that the brain's overall glucose metabolism peaks around the age of 4 years, plateaus through age 10, and begins a steady decline between 16 and 18 years, reaching adult levels late in the 2nd decade of life.

Volumetric Changes, Myelination, and White Matter Integrity

Finally, another feature of synaptic development that is being actively investigated concerns the development of white matter, which is one major constituent of brain tissue volume. Other constituents include brain gray matter (neuronal cell bodies), glial (supporting) cells, and cerebrospinal fluid. Global measures of brain volume, such as weight, potentially reflect growth in each of these structures. Brain weight increases rapidly during the first 5 years of life, reaching adult values around 10 to 12 years of age. After 5 years of age, global brain changes are relatively difficult to demonstrate, so measures that reflect structural changes must be able to detect subtle distinctions in neuronal patterning across age groups. In adults, brain anatomy and/or function can be assessed using a variety of techniques (e.g., PET, fMRI, electroencephalography, transcranial magnetic stimulation, and structural brain imaging), only some of which are appropriate for the noninvasive study of healthy children. As noted by Paus and colleagues (2001), very little is known about functional interconnectivity in the developing brain. To address this paucity of knowledge, MRI is a useful tool for investigating the anatomical features of major fiber (white matter) tracts that connect the PFC with other regions and provide information regarding functional properties of information-processing networks.

MR studies of infants have examined gray-white matter differentiation and degree of myelination (Christophe

et al., 1990; B. C. Lee et al., 1986; van der Knapp & Valk, 1990). In adults, MR images indicative of white matter structure (referred to as T-1 weighted images) are more pronounced than images that are indicative of gray matter volume (T-2 weighted images). This pattern of gray-white matter differentiation is achieved over the course of post-natal development. In the healthy newborn, there is an apparent reversal of the normal adult pattern. The infant's T2-weighted (gray matter) images look like the adult's T1-weighted (white matter) images. Late in the 1st year of life, there is poor differentiation between gray and white matter, followed by acquisition of the "early adult pattern" at around 12 months of age. In a study of 145 individuals, Giedd and colleagues (1999) reported steady increases in white matter volume from ages 4 to 22 years. Each individual was scanned twice during the developmental period. Volume increases were in the range of 12% over this time period and showed a steeper progression in boys relative to girls. A number of other researchers have similarly reported increases in white matter volume from early childhood into young adulthood (Hassink, Hiltbrunner, Muller, & Lutschg, 1992; Pfefferbaum et al., 1994; Steen, Ogg, Reddick, & Kingsley, 1997).

White matter, as assessed through MR imaging, is heterogeneous and composed of a number of components, one of which is myelin, the fatty substance that insulates axons, leading to faster conduction velocities and increased synaptic efficiency. Myelination appears to follow a pronounced temporal sequence, first observed in the cerebellum and brain stem at birth, then the posterior limb of the internal capsule, optic radiations, and splenium of the corpus callosum at 6 months, followed by the frontal, parietal, and occipital lobes at 8 to 12 months (Paus et al., 2001). Progressive changes in white matter integrity have been observed throughout adolescence and are hypothesized to be due to increases in myelination (Paus et al., 2001; Pfefferbaum et al., 1994).

Genetics and Neurochemical Variation

These general mechanisms are important to characterize, but individual variations due to differences in neurotransmitter modulation of PFC function are also possible due to genetic influences. A number of neurotransmitter systems are candidates for analyses of this type, but this discussion focuses on two. Dopamine (DA) and serotonin, each of which modulates PFC-mediated behaviors, have been considered from a molecular genetic standpoint. First, by way of background, dopamine's modulation of PFC neural activity during spatial delayed response task performance

has been demonstrated in a number of classic studies (Goldman-Rakic, 1987a; Sawaguchi & Goldman-Rakic, 1991; Sawaguchi, Matsumura, & Kubota, 1988; Williams & Goldman-Rakic, 1995). Single-unit recordings have identified task-related neurons that are active during spatial delayed response performance and that differentially increase in firing rate during the initial presentation of a stimulus cue, the subsequent delay period, and as a response is being initiated (Funahashi, Bruce, & Goldman-Rakic, 1989; Kojima & Goldman-Rakic, 1982). In monkeys, neurotoxic lesions of the dorsolateral PFC produce impaired spatial delayed alternation performance that is reversed by DA agonists (Brozoski, Brown, Rosvold, & Goldman, 1979). In addition, iontophoretic applications of DA enhance task-related PFC neuronal activity (Sawaguchi, Matsumura, & Kubota, 1988, 1990a, 1990b), and pharmacological blockade of D¹ DA receptors results in reversible decrements in delayed response performance (Sawaguchi & Goldman-Rakic, 1991). In humans, pharmacological activation of D² DA receptors, through the use of the selective D² dopamine receptor agonist bromocriptine, facilitated working memory in a visuospatial delayed response task (Luciana, Collins, & Depue, 1998; Luciana, Depue, Arbisi, & Leon, 1992). Haloperidol, a nonspecific DA antagonist, impaired working memory performance in the same group of subjects (Luciana & Collins, 1997). Others have reported transient Parkinsonian-like impairments in healthy people using sulpiride, a D² receptor antagonist (Mehta, Sahakian, McKenna, & Robbins, 1999). Agonists may reverse such deficits. For instance, bromocriptine was found to improve healthy adults' spatial memory spans (Mehta, Swainson, Ogilvie, Sahakian, & Robbins, 2001). Muller, von Cramon, and Pollmann (1998) demonstrated a facilitatory effect of a D¹ agonist in adults who completed a visuospatial delayed matching task. It is clear that dopamine's facilitation of the cellular processes that support delayed response is dose-dependent (Williams & Goldman-Rakic, 1995). Kimberg, D'Esposito, and Farah (1997) demonstrated that the optimal threshold of DA activation differs in individual human subjects. In their study, bromocriptine enhanced executive function only in individuals with low working memory capacity. Consistent with these findings, bromocriptine has been utilized to treat executive impairments in individuals with dementia (Imamura et al., 1998) and to evaluate executive function in patients with frontal lobe injuries (McDowell, Whyte, & D'Esposito, 1998). Thus, *individual differences in DA reactivity may underlie differential patterns of cognitive performance.*

Studies of DA-working memory associations in humans have focused on adults for obvious pragmatic and ethical reasons, but these associations could also be examined in developmental cohorts using noninvasive genetic (versus psychopharmacological) techniques. It has long been recognized that genes account for a substantial portion of the variability in behavior, especially in clinical conditions such as Schizophrenia (Weinberger et al., 2001).

Because these disorders are complex and likely to be mediated by interactions among candidate genes, single genes are unlikely to be specific for the disorder's presence or absence. Rather, because genes affect the biology of cells, cellular events underlie brain activity, and brain activity underlies fundamental aspects of behavior, it has been argued that genetic studies should focus on intermediate phenotypic traits, termed endophenotypes (Gottesman & Gould, 2003). These traits will not account for diagnostic classifications, but they are likely to more directly represent activity of specific genes in healthy as well as disordered people. An example is functioning of the PFC. A genetic polymorphism that impacts neurotransmission in the PFC will affect its efficiency at physiological and behavioral levels.

In theory, this hypothesis could be studied in relation to any number of candidate genes that code for various aspects of activity in major neurochemical systems. One recent focus of investigation has been the gene that encodes catechol-O-methyltransferase (COMT), a postsynaptic enzyme that methylates released dopamine to homovanillic acid (Weinberger et al., 2001). The COMT gene, located on chromosome 22q, contains a common polymorphism at position 472 (where there is a guanine-to-adenine substitution), which translates into a valine-to-methionine change in the peptide sequence (Lachman et al., 1996; Lotta et al., 1995). This change is reflected in allelic variation, whereby a given individual could possess alleles for either valine (VAL) or the methionine (MET) conversion.

At human body temperature, the MET allele has one-fourth the activity of the VAL allele, leading to decreased activity of the COMT gene and reduced catabolism of dopamine in the synapse. Furthermore, the MET and VAL alleles are codominant, so individuals with the VAL-VAL genotype have more rapid inactivation of released dopamine relative to individuals with the VAL-MET and MET-MET genotypes. Of particular importance, COMT does not appear to affect all dopamine-rich areas of the brain equivalently. It appears to be unrelated to the synaptic activity of dopamine in the striatum, due to the fact that in this region, DA activity in synapses is terminated largely by transporter reuptake into presynaptic terminals. In the PFC, DA transporter ac-

tivity is less prominent and extracellular DA is more heavily regulated by catabolic processes (Weinberger et al., 2001). Hence, we would expect COMT to impact prefrontal, but not striatal, functions that are modulated by dopamine.

COMT inhibitors improve working memory functioning in rats and in humans (Gasparini, Fabrizio, Bonifati, & Meco, 1997; Liljequist, Haapalinna, Ahlander, Ying, & Mannisto, 1997), and COMT knockout mice exhibit increased extracellular DA activity in PFC but not in the striatum (Gogos et al., 1998). They also perform better than wild-type mice under stress and on working memory tasks. Recently, Egan and colleagues (2001) reported that COMT genotype predicted performance on the Wisconsin Card Sort task in a large sample of subjects that included individuals with Schizophrenia but also a majority of healthy controls. Individuals who carried the VAL allele made more perseverative errors than those who carried the MET allele. There was the predicted effect of genetic load, in that VAL-VAL individuals performed worse than VAL-MET individuals, who performed worse than MET-MET individuals. Egan and colleague's (2001) paper has rapidly become a classic in molecular genetics. His findings have been replicated by other laboratories, using other PFC measures.

A general prediction with respect to developmental populations is that individuals who carry the VAL allele will exhibit worse performance (age-corrected) than those who carry the MET allele on measures of PFC function that can be manipulated by changes in dopamine activity. Such measures might include spatial delayed response, verbal fluency, and set shifting (Dias, Robbins, & Roberts, 1996; Luciana & Collins, 1997; Vitiello et al., 1997). In contrast, psychomotor or other striatal functions would not be influenced by COMT activity. It was recently reported that children with the MET-MET genotype performed better than those with the VAL-VAL or VAL-MET genotypes on a measure of response inhibition, which has been demonstrated in other studies of children to be DA-modulated. In contrast, measures that have not been associated with prefrontal DA activity, such as self-ordered pointing, were unaffected by the COMT genotype (Diamond, Briand, Fossella, & Gehlbach, 2004).

Although these findings are intriguing, it is, of course, unlikely that PFC function can be explained by one neurochemical parameter (e.g., catabolism of DA in the synapse) or, for that matter, by a single neurotransmitter. Indeed, Egan et al. (2001) found that COMT genotype accounts for only 4% of the variation in PFC function in an adult population. Thus, it may be that interactive models might more

strongly account for individual variations in PFC activity that are genetically modulated.

Another gene that expresses functional differences in dopamine receptor activity is the D4 dopamine receptor gene (DRD4), which has a variable number of tandem repeats in exon 3, a proline-rich coding region. The most common variants are 2 (DR2), 4 (DR4), and 7 (DR7) repeats. As compared with the DR2 and DR4 alleles, the DR7 repeat appears to blunt the intracellular response to dopamine (Asghari et al., 1995). D4 dopamine receptors are structurally similar to D2 receptors and are prominent in limbic brain structures. It has been suggested that D4 receptors in the shell of the nucleus accumbens modulate excitatory pathways and drug-induced sensitization (Hutchinson, LaChance, Niaura, Bryan, & Smolen, 2002; Svingos, Periasamy, & Pickel, 2000). The DRD4 genotypic variants have been examined in relation to novelty seeking, susceptibility to alcohol dependence, and reactivity to smoking cues (Hutchinson et al., 2002; Kluger, Siegfried, & Ebstein, 2002). Because of low baseline levels of DA stimulation, individuals who possess the long 7-repeat sequence may seek external activities that stimulate dopamine release and may be distracted by conditions that confer a high likelihood of encountering positive rewards.

Recently, there have been attempts to associate individual differences in dopamine receptor activity with psychopathology. For instance, a variant of the DRD4 gene has been associated with Attention-Deficit/Hyperactivity Disorder in several studies (McCracken et al., 2000; Swanson et al., 2000). This literature is complicated, and findings have not always been replicated across laboratories (Faraone, Doyle, Mick, & Biederman, 2001), which may be due in part to limitations associated with measuring single versus multiple gene effects to account for behavioral phenotypes.

Our research group has long advocated a model of behavior whereby dopamine acts as a general facilitator of information flow (leading to enhanced signal-to-noise ratios in information-processing networks), whereas serotonin (5HT) acts to regulate or constrain the tone of DA activity (Depue & Collins, 1999; Depue & Spoont, 1986; Luciana et al., 1998; Spoont, 1992). We have had a long-standing interest in dopamine-serotonin interactions with respect to limbic and cortical functions. With respect to PFC function, we have demonstrated constraint of DA-modulated spatial working memory functions by 5HT (Luciana et al., 1998), as well as 5HT modulation of affective information during working memory performance (Luciana, Burgund, Berman, & Hanson, 2001). To best understand how genetic variations in proteins that impact neurochemical transmis-

sion affect cognition, it may be more productive to examine combinations of genes (e.g., in the dopamine system) or to consider dopamine and serotonin neurotransmission from an interactive molecular genetic perspective. It is suggested here that this methodology has the potential to radically advance the developmental cognitive neuroscience of prefrontal function. In theory, there are several polymorphisms to consider in examining each transmitter system, although, as noted earlier, some have been more extensively investigated in relation to behavior than others.

For instance, a functional polymorphism in the promoter region of the 5HT transporter gene has been identified and examined in both human and primate behavioral genetic studies. Two common alleles, referred to as short (s) and long (l), in a variable repeat sequence of the gene have been differentially associated with impulsivity and negative affect in healthy people (Hariri et al., 2002). Possession of the long allele may be associated with disinhibitory behavior and may interact with dopamine genes to influence behavioral control under complex situations. Cultured cell lines that are homogeneous for the l-allele have higher concentrations of 5-HTT messenger RNA and express greater 5HT reuptake compared to cells that possess the s-allele (either heterogeneous or homogeneous variants). Humans with a similar genotype might be expected to be vulnerable to disinhibition because their higher levels of 5HT reuptake leave less serotonin available in the synapse. In contrast, humans who carry the s-allele are likely to display high levels of anxiety and fearful behavior as compared to those who are homozygous for the l-allele.

In a relatively recent study (Auerbach et al., 1999), it was reported that infants homozygous for the s-allele of the 5HT transporter gene and lacking the long repeat sequence of the DRD4 gene demonstrate maximal levels of negative emotionality and distress in daily (novel) situations. This finding could be replicated in other samples by examining DRD4 and 5HT transporter genotypes in relation to emotional characteristics, as revealed by questionnaires or behavioral tasks that require behavioral regulation. In addition, whether individuals who carry the s- versus l-alleles of the 5HT transporter vary in PFC-guided behaviors on the basis of whether they carry the MET or VAL COMT allele and/or the 7-repeat sequence of the DRD4 receptor could be investigated.

Another intriguing line of molecular genetic research concerns how genotype interacts with the environment to influence behavioral outcomes. It was recently reported that individuals who carry the s-allele of the 5HT transporter gene exhibited more objectively verified stressful life events, a higher number of depressive symptoms, and

more suicidal thoughts in relation to these stressors than individuals who carry two copies of the l-allele (Caspi et al., 2003). Animal models have likewise demonstrated an interaction between the s-allele and the experience of a stressful rearing environment (peer rearing versus mother rearing) on several aspects of behavior, including alcohol preference, aggression, and hypothalamic-pituitary-adrenal activity in nonhuman primates (Barr, Schwandt, Newman, & Higley, 2004). In many cases, these associations are moderated by gender as well as age of the animal when tested.

In summary, the study of genotype-environment-behavior interactions in development, as informed by knowledge regarding the life span development of the PFC, has the potential to contribute to the nature-nurture debate by addressing how much variance in the PFC's functional development can be attributed to genetic (versus environmental) sources of influence.

Implications: Can We Identify Critical Periods in Prefrontal Cortex Development?

Overall, neurodevelopmental studies suggest the existence of two critical periods in postnatal brain and PFC development, each of which corresponds to a time of accelerated growth and synaptic refinement. One period overlaps the burst of synaptogenesis that occurs in late infancy/early childhood. It has been demonstrated that rats who are raised in impoverished learning environments have decreased synaptic density relative to those raised in more stimulating environments (Greenough & Black, 1992). In theory, the more synapses that you have and use, the less you lose later on. Hence, the other critical period corresponds to adolescence, when synaptic elimination and the progression of white matter development serve to stabilize developing information-processing networks at a functional level that will characterize most of adult life. Prior to describing the course of the PFC's apparent behavioral maturation, recent views on the functional role of the PFC are described.

THE FUNCTIONAL ROLE OF THE PREFRONTAL CORTEX

It is generally accepted that the prefrontal cortex underlies the highest level of human cognition, including planning and complex forms of goal-directed behavior. Surprisingly, PFC function has been assessed using very simple behavioral tasks, such as Jacobsen's (1935) spatial delayed response task. Numerous studies have replicated Jacobsen's

basic finding of recent memory deficits following dorsolateral prefrontal lesions (Goldman & Rosvold, 1970; Goldman-Rakic, 1987a), and many other studies have demonstrated that cells in this region are active during the delay phase of task performance (Funahashi et al., 1989; Fuster & Alexander, 1971; Niki, 1974; Sawaguchi et al., 1990a). In the monkey, lesions of the dorsolateral prefrontal cortex in the region of the principal sulcus (Brodmann's area 46) impair behavioral performance but only under delayed response conditions (Diamond & Goldman-Rakic, 1989; Goldman-Rakic, 1987a, 1987b). That is, immediate responding to reward-salient objects is not obviously affected. Spatial delayed response is also commonly referred to as *spatial working memory*. How working memory differs from other short-term forms of memory has been the subject of numerous books and articles (Baddeley, 1992; Fuster, 1997).

Working memory or "working with memory" (Moscovitch, 1992) is conceptualized as a highly active process, limited in its capacity, that requires the maintenance or manipulation of internally represented information to guide behavioral responses toward future goals (Baddeley, 1992; Fuster, 1997; Goldman-Rakic, 1987a). It involves a juxtaposition of attention, memory, and perception. For example, in the delayed response paradigm, the animal actively and effortfully works to maintain knowledge of the hidden stimulus, presumably because the stimulus object is highly desired. Given that the dorsolateral prefrontal cortex appears critical for spatial working memory performance, it was assumed for a time that all types of working memory (e.g., those that involve memory for nonspatial cues) were similarly dependent on the prefrontal cortex. Two theories are currently debated regarding whether this notion is true.

As described earlier in this chapter, the PFC can be parcellated into two general regions: the dorsal region and the ventral region. Within the dorsal and ventral areas, a further division into lateral and medial areas has been proposed. Furthermore, it has been suggested that the lateral PFC is devoted to working memory and cognitive processing (Braver & Cohen, 1999; Miller & Cohen, 2001) and that the ventromedial PFC (of which the orbitofrontal cortex is a part) controls the emotion-cognition interface (Happaney, Zelazo, & Stuss, 2004). The first theory regarding how the PFC subdivisions control behavior states that there is *domain-specific regional specialization* within the PFC (Goldman-Rakic, 1988). Accordingly, the dorsolateral prefrontal cortex in the region of the principal sulcus is critical for the representation of spatial information, and inferior regions are specialized for representing fea-

tures of objects, such as their color and shape (Goldman-Rakic, 1988; Wilson, O'Scalaidhe, & Goldman-Rakic, 1993). According to this theory, the dorsal-ventral divisions of the PFC represent anterior extensions of the dorsal (spatial) and ventral (object) sensory processing pathways. This view is currently highly controversial, largely because it has not been fully supported by single unit recording and human neuroimaging studies (Miller & Cohen, 2001). Available data more strongly support a hemispheric account for how spatial versus object cues are processed in working memory. That is, the right prefrontal cortex is relatively specialized for spatial processing, and the left prefrontal cortex is specialized for nonspatial (verbal) processing (Fletcher & Henson, 2001).

A second theory, which has derived most of its support from human neuroimaging data (D'Esposito et al., 1998; Kessels, Postma, Wijnalda, & de Haan, 2000; Petrides, 1995), focuses largely on the functional specialization of the lateral PFC. It proposes regional differences in how the lateral PFC handles behaviors that demand high versus low *levels of processing*. Regardless of whether the information to be used in working memory is spatial, verbal, or object-related, the ventrolateral PFC may be recruited during low-level ("maintenance-only") tasks, whereas the dorsolateral PFC is recruited when one must not only maintain information in working memory but also manipulate it or intensively monitor performance ("maintenance-plus") tasks.

Thus, these models disagree as to whether the PFC is organized according to domain (e.g., spatial, verbal, object information) or level of processing. Both models emphasize the integral role of the lateral PFC (ventral and/or dorsal) in functions that require the cross-temporal integration of sensory cues with soon-to-be-executed responses. Other classic empirical measures that have been used to assess the integrity of similar functions in adult humans include temporal judgments (e.g., which item appeared more recently in a sequence; Milner, Corsi, & Leonard, 1991), self-ordered search tasks (Petrides & Milner, 1982), look-ahead planning tasks (Shallice, 1982), and measures of set shifting in which several different response attributes must be held simultaneously in mind and used to guide behavior in the midst of external feedback (e.g., the Wisconsin Card Sort task; Milner, 1963; Figure 7.2). When each of these tasks is dissociated into its component parts, it becomes obvious that the ability to maintain information across temporal intervals of time and link this information with appropriate responses clearly involves a number of cognitive operations, including short-term memory, attention, and the active suppression of competing information.

Given the nature of these functions, it is not surprising that another major aspect of behavior that has been associated with prefrontal functioning is behavioral inhibition, the ability to forgo immediate prepotent responding in favor of more strategic evaluative choices. As evident in the case of Phineas Gage (Harlow, 1868), damage to the anterior-most region of the PFC results in behavioral impulsivity and seeming imperviousness to socially appropriate behavior (Fuster, 1997). Experimentally, the capacity for behavioral inhibition has been assessed through variants of the go/no go task, in which the correct response to each trial is signaled by a warning stimulus that tells a research subject to either "go" (make a particular response) or "not to go" (inhibit the typical response or execute an alternative response), with the "go" response being prominent (Diamond, 2001). Other tasks that index similar functions include conflict monitoring tasks that set up a competition between prepotent responses and more effortful, but not obviously correct, ones (e.g., the Color-Word Stroop Test; Perret, 1974).

Behavioral inhibition is, in many respects, ubiquitous. It is difficult to imagine a task that does not require some level of inhibition of responses or maintenance of attention in the face of potential external or internal distractions. Adele Diamond (1990a, 1990b) has long advocated the view that the dorsolateral PFC is required when both memory and inhibitory control are simultaneously recruited by a task. Together, working memory and behavioral inhibition tasks can be said to require cognitive control over behavior. Cognitive control, as a descriptor and as a construct, is currently receiving a great deal of empirical attention in studies of PFC function.

Cognitive control is defined as the ability to flexibly shape and constrain thoughts and actions in order to accomplish goals (Bunge, Dudukovic, Thomason, Vaidya, & Gabrieli, 2002). It requires that one encode relevant environmental stimuli, select those that are appropriate based on weighing motivational signals against long-term goals, hold this important information in mind across time while ignoring extraneous distractions, select actions that are appropriate to the desired goal, and execute those actions appropriately. By definition, then, cognitive control (like working memory) is a complex construct that incorporates memory, attention, and inhibitory control. Failures of cognitive control are often associated with the presence of compelling distractors. These distractors impair one's ability to focus on long-term goals, and as a consequence, they adversely impact decision making. Because cognitive control substantially overlaps with the construct of behavioral inhibition, it tends to be assessed via the same types

of conflict monitoring tasks (e.g., the Stroop Color-Word Naming Task) that require individuals to ignore irrelevant stimuli or response inhibition tasks that require the ability to inhibit prepotent response tendencies (Braver, Barch, Gray, Molfese, & Snyder, 2001; Bunge et al., 2002; Casey et al., 1998; Diamond, 1990a; Dempster, 1992; Luna et al., 2001; Ridderinkhof & van der Molen, 1997). However, the construct of cognitive control (sometimes also called “effortful control”) is broader than these tasks imply, also encompassing working memory and the ability to execute decisions under highly salient emotional situations. Each of these functions relies heavily on the prefrontal cortex in conjunction with striatal, limbic, and posterior cortical regions (Casey et al., 1997; Goldman-Rakic, 1987a; Diamond, 1990a, 1990b).

As behavioral situations become more complex, the PFC must integrate activity within and across these regions. This view readily lends itself to the next major empirical and theoretical shift in the assessment of PFC function, one that posits a mechanism through which cognition and emotion interact in the service of goal-directed behavior. Cognitive control under complex conditions of high emotional salience demands a maximal level of PFC integration. This integration requires communication *within* the PFC (between its lateral and medial regions) as well as orchestration of information that is being processed within posterior cortical and subcortical regions.

The capacity of the PFC to integrate multiple sources of information and to orchestrate appropriate responses to that information is critically important from a developmental perspective. Consider, for instance, the following scenario: Imagine that you are the parent of a typical teenager. You discover that he or she attended an unchaperoned party instead of studying for the SATs. You later hear stories from other parents to suggest that there was drug and alcohol use at the party as well as sexual activity. Can you be confident in your child’s ability to make safe decisions? If not, will you blame the situation? Parenting? Genes? Or are such lapses normal? One thing seems highly probable: Without adequate PFC regulation, an individual would be expected to behave based on evaluations of the immediate context. Longer-term consequences could, of course, be life-lasting, but these are not necessarily considered. Therefore, probing sources of influence over how such decisions are made during the course of development and their neural substrates has numerous public health, societal, and clinical neuroscientific implications.

From a neurobiological perspective, this situation might proceed as follows: When a child encounters positive stimuli in the form of friends and other features of a highly

stimulating environment, limbic structures within the basolateral forebrain (amygdala, septum, and nucleus accumbens) are activated to encode each stimulus according to its motivational salience. While the amygdala plays a central role in tagging various stimuli according to their incentive value, the nucleus accumbens, using dopamine as its primary transmitter, translates this motivational information into behavioral actions through its connections with motor output centers in the striatum (Depue & Collins, 1999; Mogenson, Jones, & Yim, 1980). These actions might include risk-taking behaviors such as drinking alcohol and using drugs. This information is also relayed to the ventromedial prefrontal cortex, where contingencies related to positive and negative reinforcement are evaluated. That is, whether the behaviors continue will depend on evaluations of their benefits versus costs.

In parallel fashion, posterior cortical regions within the temporal and parietal lobes extract relevant stimulus cues from the environment related to stimulus features and their locations, and through interactions with the thalamus, attentional resources are directed toward these stimuli. The prefrontal cortex receives all of this information from the thalamus, sensory association regions, and the limbic-PFC interface and acts on it. If a situation is sufficiently complex, then the dorsolateral PFC (DLPFC) may be recruited to orchestrate its various inputs and to guide the appropriate selection of actions. As part of this action selection process, the DLPFC exerts inhibitory control over the nucleus accumbens-motor output interface, thereby mediating the extent to which overt behavior is swayed by motivational impulses. Thus, the DLPFC is an executive center for self-monitoring, emotional control, and action selection. It relies on the ventromedial region of the PFC for the accurate communication of data regarding environmental contingencies and whether behavioral responses must be changed in light of those contingencies.

It might be helpful at this point to interject some information regarding the ventromedial PFC (VMPFC). Depending on the species being studied, two behavioral paradigms have been commonly used to assess VMPFC activity. The first involves discrimination and reversal learning, and the second involves extinction training (Happeney et al., 2004). In reversal learning paradigms, an individual is trained through reinforcement to repeatedly select one of several stimuli, and after the individual overlearns that a given stimulus signals reward, the contingency changes such that the currently reinforced stimulus is no longer reinforced, and selection of a previously unreinforced stimulus leads to reward (Dias et al., 1996; Rolls, 1999; Rosenkilde, 1979). Extinction learning tasks are somewhat similar in that a response is

reinforced until a learning criterion is met, then the reinforcement is withheld. Animals as well as humans with damage to orbitofrontal/ventromedial regions show resistance to extinction and continue to respond to the previously learned stimulus even though it is no longer being reinforced (see review by Rolls, 2004). Rolls (2004) suggests that the orbitofrontal PFC is primarily engaged when one is called on to reappraise the affective significance of stimuli and subsequently, to change behavior in the face of rapidly changing social or experiential contexts.

These findings, as well as numerous case histories similar to that of Phineas Gage's, have led researchers to focus on how the ventral and orbital regions of the PFC control motivational or affective aspects of decision making (Happeney et al., 2004). The primary challenge in this line of inquiry is to create laboratory measures that approximate the types of real-world lapses in judgment that individuals with ventral/orbital PFC lesions tend to make. One type of task, currently considered the state of the art in VMPFC assessment, presents individuals with choices that pit immediate rewards against future punishments (e.g., the Iowa Gambling Task [IGT]: Bechara, Damasio, Damasio, & Anderson, 1994). To perform successfully, one must appreciate four separate response contingencies (corresponding to four decks of cards that are simultaneously presented; see Figure 7.3), remember these contingencies over time, distinguish immediate

from long-term outcomes, and adjust behavior accordingly. Through the use of the IGT or analogues, decision-making deficits have been identified in VMPFC patients, pathological gambling patients, and drug and alcohol abusers (Bechara, Damasio, & Damasio, 2000; Bechara, Tranel, & Damasio, 2000; Cavedini, Riboldi, Keller, D'Annunzio, & Bellodi, 2002; S. Grant, Contoreggi, & London, 2000; Mazas, Finn, & Steinmetz, 2000; Rogers et al., 1999). PET scans reveal alterations in VMPFC glucose metabolism (Volkow et al., 1991).

In summary, the PFC's major function is to assist the organism in achieving behavioral control so that future goals can be attained. Available data suggest that when behavioral control is required, the DLPFC is recruited. When that control is required in the context of highly salient emotional contexts (as is typically the case in most real-life nonexperimental circumstances), the ventromedial and dorsolateral regions of the PFC must work together to regulate behavior. Because control processes are inherently integrative, requiring that multiple pieces of information are managed, our group has preferred to conceptualize them in terms of cognitive multitasking (Luciana & Nelson, 1998). What, then, is known regarding the development of these processes?

A DIMENSIONAL VIEW OF THE FUNCTIONAL DEVELOPMENT OF THE PREFRONTAL CORTEX

Figure 7.3 The Iowa Gambling Task requires individuals to choose from “decks” of cards to obtain monetary rewards. Two decks are advantageous in that they yield high net gains in the long run but small payoffs trial-by-trial. Two decks are disadvantageous in that they yield high net losses over time but seemingly high immediate payoffs. High-quality decision making, as assessed by the task, requires that the separate cognitive contingencies (or rules) that differentiate each deck are appreciated and that these contingencies are managed relative to the desire for high immediate rewards. It is suggested here that this task requires a high level of cognition-emotion integration that should recruit ventromedial as well as dorsolateral prefrontal regions.

Available evidence suggests that cognitive control emerges dimensionally over the course of infant and child development. Recent data from our own and others' laboratories suggest that it may not asymptote until the 3rd decade of life. In the following section, several measures are referenced that have been incorporated in developmental studies. Table 7.1 includes a summary of these measures, their suggested neural correlates, and references to studies where each measure has been used. It is beyond the scope of this chapter to cover every possible test of prefrontal or executive function that has been used with developmental populations, but the following discussion highlights work that is considered classic in the field.

Infancy

Prefrontal function in the infancy period has been assessed using tasks that have rich histories in child developmental research as well as experimental neuropsychology. Surprisingly, tasks that were conceived in these seemingly disparate areas of inquiry overlap considerably in their

TABLE 7.1 Neurocognitive Measures of Prefrontal Function in Infants, Children, Adolescents, and Adults

Task Name	Applied to Age Group	What It Measures	Selected References
A-not-B Object Permanence Task	Infants	Spatial working memory	Piaget (1936); Diamond (1990a)
Object Retrieval Task	Infants	Inhibition	Diamond (1990b)
Dimensional Change Card Sort	Preschool	Set shifting	Zelazo et al. (1996)
Luria Tapping Task	Preschool	Inhibitory motor control	Luria (1966); Diamond (2001)
Day-Night Stroop Task	Preschool	Conflict monitoring; inhibition	Levin et al., 1991; Gerstadt et al. (1994)

Spatial Self-Ordered Search	Children–Adults	Strategic searching; self-monitoring; spatial memory	Owen et al. (1990); Luciana & Nelson (1998)
Hungry Donkey Task	Children–Adults	Delayed gratification; reward-related decision making; contingency learning; prosocial behavior	Crone et al. (2003)
Iowa Gambling Task	Children–Adults	Delayed gratification; reward-related decision making	Bechara et al. (1994); Hooper et al. (2004); Overman et al. (2004)
Reversal Learning Tasks	Preschool–Adult	Response reappraisal and relearning of stimulus-response associations	Dias et al. (1996); Overman et al. (1996)
Resistance to Extinction	Preschool–Adult	Unlearning of previously learned associations	Happeney et al. (2004)
Spatial Delayed Recognition	Children–Adults	Recognition memory for spatial locations	Klingberg et al. (2002)
N-Back	Children–Adults	Cognitive control, inhibition, attention, working memory	Kwon et al. (2002)
Rey Auditory Verbal Learning Task	Children–Adults	Learning of a repeatedly presented word list	Sowell et al. (2001)

Note: This table is not meant to represent an all-inclusive list of tasks that have been utilized to measure frontal lobe function in individuals across the life span. However, these are measures that have been used in some of the more frequently cited studies.

demands. For instance, Adele Diamond noted a correspondence between the traditional spatial delayed response task and a measure that had been used for years in the field of child development: Piaget's (1936) A-not-B task. Piaget's AB task involves hiding an object of interest in one of two locations, in view of an infant. After a brief delay, the infant is permitted to retrieve the object. The location

of hiding is varied across trials, and the infant's sense of object permanence is inferred if he or she is correct in finding the object when it is not in full view. Diamond (1990a) reported that 7- to 8-month-old infants are able to correctly retrieve objects from the first-baited location when delays are between 1 and 3 seconds in length. However, on some trials, they make the classic A-not-B error.

This error occurs over the course of two successive trials. On the first trial, the object is hidden at location A and, typically, it is successfully retrieved by the infant. On the next trial, the object is hidden at location B, again in view of the infant. The infant makes an error by searching the previously rewarded location A, despite having clearly seen that the object was hidden in a different location. This error pattern is quite robust, and the precise reason for it is one of the most thoroughly researched issues in child development. No agreement has been reached to account for the infant's behavior, which gradually improves as the infant can tolerate longer delays with increasing age. By 12 to 13 months of age, the infant can perform successfully at 10-second delays before making the A-not-B error. Because the infant performs in a manner that is similar to that of monkeys with prefrontal lesions, Diamond and Goldman-Rakic (1989; Goldman-Rakic, 1987b) suggested that infants' development of object permanence is rooted in the maturation of prefrontal regions and associated networks. If this is the case, then infants' performance patterns on A-not-B raises many puzzling issues.

For instance, one anomaly is that performance in human infants is dependent on the response mode employed (Diamond, 1990a, 1990b, 2001). When accuracy of performance is measured by direction of gaze rather than by reaching behavior, infants often appear to "know" the correct location of the hidden object even when their manual responses are incorrect. Correct performance can also be facilitated by shortening the delay interval, by allowing the infant to physically orient himself or herself toward the correct location, by using landmarks to target the correct hiding location, or by using a minimal number of hiding locations. In 9-month-olds, the number of A-trial presentations influences whether or not an error is made at the first B-trial presentation (Marcovitch, Zelazo, & Schmuckler, 2002). Indeed, what these findings seem to demonstrate is that when the task is altered in ways that decrease the demands for cognitive control, or multitasking, performance improves.

A second task in which performance accelerates at the same rate as delayed response in human infants is the *object retrieval* task (Diamond, 1990b, 2001). In this task, a desired object is placed inside a clear-sided box that has an opening only on one side. The infant's task is to retrieve the object. When the infant sees the toy directly through the open side, he or she is able to reach correctly to retrieve it. However, if the infant views the toy through a clear but occluded side, he or she exhibits a preferential tendency to try to reach through the occluded side to retrieve the toy. Hence, to perform the task correctly, the infant must inhibit this prepotent response tendency, disengage his or her

reaching behavior from his or her looking behavior, manipulate the box, and reach through its open side to retrieve the toy. This sequence requires the infant to integrate the conflicting demands of looking versus reaching behavior (Diamond, 1990b, 2001).

Individual human infants and infant rhesus macaques develop the skills necessary to perform both A-not-B and the object retrieval task at the same rate over the same developmental period of time (between 6 and 12 months in human infants and 2 to 4 months in macaques; Diamond, 1990a, 1990b; Diamond & Goldman-Rakic, 1989). Moreover, improved performance on both tasks in human infants correlates with changes in frontal EEG activity (Bell & Fox, 1992, 1997). Diamond (1990a, 1990b) suggested on the basis of these data that the dorsolateral prefrontal cortex is engaged when both inhibitory control and memory are required in the same behavior.

To summarize, Diamond's classic studies, which have relied on an integration of animal, developmental, and neuropsychological methods, suggest that the prefrontal cortex is behaviorally engaged in the monkey and human beginning in late infancy. By the time children reach preschool age, the tasks that have been informative in mapping the infant's initial expression of cognitive control processes are no longer challenging. Therefore, it has been necessary to develop slightly more complex measures to measure cognitive changes in preschool and school-age children.

Preschool and Middle Childhood

These measures have included set-shifting tasks, measures of behavioral conflict resolution, and attention tasks. When healthy adults perform set-shifting tasks such as the Wisconsin Card Sort, they are able to correctly sort cards that vary on at least three stimulus attributes (color, number, and/or shape) in response to verbal feedback. Children are unable to manage this level of complexity. On a less-demanding but analogous measure of set shifting, the *dimensional-change card sort*, it was found that 3-year-old children were able to correctly sort cards based on the first of two possible criteria that they were given. They were capable of making either conceptualization when it was presented first. However, when they were required to shift set and sort the cards using the second stimulus attribute, they persisted in sorting according to the first dimension (Kirkham & Diamond, 1999; Zelazo, Frye, & Rapus, 1996).

Thus, the ability to appreciate at least two stimulus attributes that jointly apply to objects (e.g., that the object can be referenced by either its color or its shape) is present

by age 3. However, holding both attributes in mind at the same time and shifting between them is difficult. Between the ages of 3 and 6, children become progressively more adept at the task, first succeeding when they must switch between two sorting criteria at ages 4 to 5, and then becoming able to sort among three possible criteria by the age of 6. Again, children's performance on this task illustrates that the capacity for cognitive multitasking increases in a dimensional fashion in preschoolers.

The same general trend is evident for other aspects of behavioral inhibition, as exemplified by an analogue of the Stroop Color-Word Task. This task, called the Day-Night Stroop Task, was first used by Levin (Levin et al., 1991) but then modified in Adele Diamond's laboratory (Gerstadt, Hong, & Diamond, 1994). In the conventional Stroop task, individuals must read words that consist of color names (e.g., BLUE, RED, GREEN). Conflict is created by printing the words in colored fonts that are different from the word meanings (e.g., the word BLUE printed in green ink). In the Day-Night Stroop, children must respond to two cards, one of which illustrates a picture of the sun and the other that illustrates the moon. The conflict condition occurs when children are required to say "night" in response to the sun and "day" when presented with the picture of the moon. This simplified task variant eliminates the reading ability that is necessary to complete the adult version, thus reducing the child's information-processing load. The Day-Night Stroop is difficult for 3- to 4-year-olds but relatively easy for 6- to 7-year-olds. Similarly, on measures of motor inhibition (e.g., Luria's tapping task: Luria, 1966), children perform at a similar rate as on the Day-Night Stroop, improving in their speed and accuracy between the ages of 3 and 7 years (see Diamond, 2001; Diamond & Taylor, 1996; Passler, Isaac, & Hynd, 1985). Thus, through the preschool period, abilities that are apparently dependent on the PFC become increasingly well-developed, although those items and/or tasks that differentiate among children of different ages demand relatively little in the way of multitasking ability (at least as viewed from an adult perspective).

This steady developmental progression continues during middle childhood. Welsh, Pennington, and Groisser (1991) studied 110 children between the ages of 3 and 12 years using a battery of executive function measures, including visual search, verbal fluency, motor planning, the Tower of Hanoi, the Wisconsin Card Sort, and the Matching Familiar Figures test. On the more difficult tasks, including the Wisconsin Card Sort and 4-disk Tower of Hanoi tasks, an adult level of performance was reached between 10 years

(Wisconsin Card Sort) and adolescence (Tower of Hanoi, verbal fluency, and motor sequencing).

Most studies have relied on the nature of their experimental tasks to infer brain-behavior relations in children. However, Bunge et al. (2002) expanded on this general approach by examining patterns of brain activation in children, as compared to adults, who were administered measures of cognitive control. They reported inferior performance in 8- to 12-year-old children as compared to adults on no-go and incongruent trials of a flanker task.

The flanker task generally proceeded as follows. Flankers are arrows that point either to the left or to the right. On each trial, children viewed five stimuli (arrows) arranged in a row. The middle stimulus was a flanker that pointed right or left, and the general task was to look at the middle arrow to decide whether to push a response button that was on the left or the right. The other stimuli serve as distractors. On congruent trials, a right-sided button was pressed if the arrow pointed right, and a left-sided button was pressed if the arrow pointed left. On incongruent trials, the task was to respond in the direction opposite to where the arrow pointed. Finally, on no-go trials, subjects were asked to refrain from responding.

Children demonstrated a greater interference effect as indicated by slower response times across all task conditions. In adults, interference suppression activated the right ventrolateral PFC, the anterior insula, inferior parietal lobule, and putamen. In children, the left ventrolateral PFC and insula were activated along with the right inferior parietal lobule. In children, better task performers exhibited greater left PFC activation. In adults, response inhibition activated a number of PFC regions, including the bilateral ventrolateral and dorsolateral regions as well as the anterior and posterior cingulate, but these areas were not significantly activated in children as a whole. However, children who performed particularly well activated a subset of the same regions that were activated in adults.

Hence, interference suppression, strongly modulated by the anterior insular cortex, may mature to adult patterns of brain activity more quickly than response inhibition, mediated by a distributed network that includes the lateral PFC and anterior cingulate. Other studies have demonstrated robust activation of the lateral PFC in prepubescent children during response inhibition (Casey et al., 1997; Vaidya et al., 1998). However, because the study by Bunge et al. (2002) found substantial differences in 8- to 12-year-olds versus young adults, a major transition in the capacity for cognitive control may occur between the ages of 12 and 19. Similarly, Tamm, Menon, and Reiss (2002) studied go/no

go performance in a small ($n = 19$) sample of 8- to 20-year-olds and found that, although age did not predict absolute accuracy of performance, it was related to performance speed or efficiency in inhibitory control. Moreover, as compared to younger subjects who activated extensive regions of the dorsolateral PFC while they performed the task, older ones showed a more focal and more restricted pattern of activation.

Interpretation across studies and across age groups is complicated by the fact that few measures of cognitive control can be (or have been) applied without alteration to children in all phases of development. Our laboratory has attempted to remedy this difficulty by using an automated task battery that not only has been investigated according to its brain-behavior correlates but includes measures that can be interpreted from a dimensional perspective.

Computerized Assessments of Frontal Lobe Function

We recently used the Cambridge Neuropsychological Testing Automated Battery (CANTAB) to study PFC functions in children ages 4 to 12 years as compared to young adults (Luciana, 2002; Luciana & Nelson, 1998, 2002). The CANTAB is a computerized neuropsychological assessment battery that was originally developed to diagnose dementia in elderly individuals (Sahakian & Owen, 1992). The most current version operates through the Windows operating system and utilizes touch screen technology. The battery consists of 13 subtests that include measures of motor skill, visual attention, memory, and working memory. All task stimuli are nonverbal, being geometric designs and simple shapes, and language proficiency is necessary only to understand the instructions prior to task initiation. The validity of the CANTAB for assessing brain-behavior relations in adults has been supported by numerous studies of patients with brain lesions, degenerative disorders, and psychiatric illness (Fowler, Saling, Conway, Semple, & Louis, 1997; Owen, Iddon, Hodges, Summers, & Robbins, 1997; Owen, Roberts, Polkey, Sahakian, & Robbins, 1991; Rahman, Robbins, & Sahakian, 1999). The impacts of psychopharmacological treatments on performance have also been examined (Coull, Middleton, Robbins, & Sahakian, 1995; Elliott et al., 1997; Lange et al., 1992). Recently, fMRI and PET have provided information regarding the neural substrates underlying adults' performance on several tasks (A. C. H. Lee, Owen, Rogers, Sahakian, & Robbins, 2000). These findings indicate that the CANTAB is sensitive to the presence of brain dysfunction in adults and that discrimination among subtypes of brain disorder is possible using profile interpretation. For

example, patients with frontal versus temporal lobe pathology differ in their performance on CANTAB's measures of working and recognition memory (Owen, Morris, Sahakian, Polkey, & Robbins, 1996; Owen, Sahakian, Semple, Polkey, & Robbins, 1995).

An even more recent development has been the use of the CANTAB to study neuropsychological function in pediatric populations (Hughes, Russell, & Robbins, 1994; Luciana, Lindeke, Georgieff, Mills, & Nelson, 1999; Luciana & Nelson, 1998, 2000, 2001; Luciana, Sullivan, & Nelson, 2001; Ozonoff, 2001). The battery has generated interest among developmental cognitive neuroscientists primarily because it emphasizes the assessment of executive functioning, including measures of planning, set shifting, spatial working memory (self-ordered search), and nonverbal memory span. We examined the feasibility of using the CANTAB to assess executive functions in a large healthy pediatric sample with the initial goal of determining the age limits of the battery's use and whether it could be administered without alteration to children. Nearly 400 typically developing children between the ages of 4 and 12 years were tested (Luciana & Nelson, 1998, 2002). Six of 13 subtests from the CANTAB were administered. In general, children found the computerized testing format motivating, and task performance was comparable in children who were native versus nonnative English speakers when English was the language used to present each task (Luciana & Nelson, 2000, 2002). A significant strength of the battery is that children can be tested on the same tests and using exactly the same item sets that are employed in adult studies. Thus, across laboratories, this battery has been successfully used, without modification, to measure cognitive functions in individuals from age 4 to over 90 years. This feature permits complex cognitive functions to be dimensionally measured from the time they are first emerging to the time when they are maximal in processing multiple pieces of information to the time when they decline due to aging. In addition, trajectories across different tasks (e.g., the life span development of planning versus the development of recognition memory) can be examined and compared within and between age groups.

Our data indicate that planning and working memory skills have not reached adult levels by the age of 12 years based on analyses of the self-ordered search and Tower of London tasks. These tasks are selected for discussion because they are relatively complex in their demands and require high levels of cognitive control for performance to be successful. Self-ordered tasks were first described by Petrides and Milner (1982) in their studies of neurological

patients with frontal lobe lesions. On the CANTAB's self-ordered search task, an examinee is presented with an array of squares and told to find tokens that are hidden within the squares. The search is conducted by touching a square to "open" it. Sometimes the square is empty, and sometimes it contains a colored token. Each square is baited only once, but the examinee does not know, after any given selection, where the next token will appear. A return to an already-baited location constitutes an error. Thus, efficiency of searching is required, as is memory for locations that have been successfully searched. The task ranges in difficulty from two-item searches, generally very easy even for 4-year-olds, to eight-item searches that healthy young adults find challenging. Moreover, a strategy score is derived based on how well the examinee is able to conduct each search sequence in an organized way (Owen, Morris, Sahakian, Polkey, & Robbins, 1996). Both frontal and temporal lobe lesions are associated with mnemonic errors, but deficient strategy use has been exclusively associated with frontal lobe impairment in neurological patients (Owen, Morris, et al., 1996). When an efficient strategy is utilized, the mnemonic demands of the task are minimized. Accordingly, individuals with less than optimal functioning of the frontal lobe must depend more heavily on their memory skills in progressing through searches that involve large item sets. As expected, in healthy adults, memory span is inversely correlated with the number of forgetting errors on the task.

The Tower of London is a planning task. It requires the test taker to move colored balls, adhering to a set of rules regarding how the balls can be moved, to match a display model. At the beginning of each trial, the participant is told how many moves are minimally needed to solve that problem. The primary variable of interest is the number of problems that can be solved in the minimum possible number of moves (Shallice, 1982). The CANTAB version of the task includes problems that range in difficulty from two to five moves. In theory, one must take some time to plan the first move to solve each problem efficiently. Planning times are also calculated.

The Tower of London and self-ordered search tasks are similar in that they both require behavioral organization and/or self-monitoring to complete their most difficult items with maximal efficiency. Children's performance on both tasks has been informative as to the course of PFC maturation. First, 4- to 12-year-old children are able to complete the easiest (2- and 3-item search) trials of the self-ordered search task in a manner that is not statistically distinct from adult performance, verifying that executive skill is present by the age of 4 years. However, by adminis-

tering the task in its entirety, it is evident that several important behavioral distinctions are not evident until the most difficult (6- and 8-item search) trials are examined. By the age of 12 years, children still have not reached adult levels of task performance on these items in terms of error scores or strategy use. This finding is consistent with other reports regarding the neuropsychological development of frontal lobe functions in pubescent children (Passler et al., 1985; Welsh, Pennington, & Groisser, 1991) and with the theorized emergence of formal operational thought in early adolescence (Inhelder & Piaget, 1958). The same pattern of performance is demonstrated on the Tower of London task in terms of the ability to solve the most difficult (5-move) problems in a maximally efficient manner.

On the basis of these findings, our group suggested that future studies should focus on cohorts of adolescents in the pre- to postpubertal transition, as compared to adults, to identify when adult levels of competence are reached under conditions that demand a high level of information processing and self-organization. Arguably, these are the conditions that best approximate real-world situations that challenge an individual's capacities for cognitive control.

Adolescence to Young Adulthood

There are surprisingly few comprehensive studies that have assessed working memory and cognitive control processes in adolescents between the ages of 12 and 20 years. The frequently cited conclusion that these functions reach maturity during adolescence is largely derived from studies such as the Welsh et al. (1991) and Luciana and Nelson (2002) studies that report performance differences between prepubescent children and young adults. What is known is that a number of brain changes are occurring during the adolescent period and that because of the nature of these changes, improvements in executive control (presumed to be PFC-mediated in adults) are expected. For instance, the PFC undergoes continued structural and neurochemical refinement during adolescence (Chugani, 1998; Spear, 2000). Although gross structure and overall brain volume are relatively stable by the age of 5 years (Giedd et al., 1996; Paus et al., 2001; Reiss, Abrams, Singer, Ross, & Denckla, 1996), neuroimaging studies in humans and histological studies of animals consistently indicate that adolescence is characterized by gray matter loss in numerous areas of the cortex and that such loss is consistent with synaptic pruning (Giedd et al., 1999; Pfefferbaum et al., 1994; Sowell, Thompson, Tessner, & Toga, 2001). Sowell and colleagues (Sowell, Thompson, et al., 2001; Sowell et al., 2003) have demonstrated that gray matter

loss in the PFC occurs at a more protracted rate than similar loss in the parietal cortex. At the same time, white matter development, particularly myelination, also continues throughout adolescence (Caviness, Kennedy, Richelme, Rademacher, & Filipek, 1996; Giedd et al., 1999; Pfefferbaum et al., 1994) and may be particularly pronounced in the frontal lobe (Reiss et al., 1996).

Unfortunately, there have been few attempts to directly link these structural changes with functional developments. Sowell, Delis, Stiles, and Jernigan (2001) reported that frontal gray matter decline predicted delayed verbal memory performance as well as visuospatial memory in 35 children age 7 to 16 years. In addition, recent functional neuroimaging studies have suggested that changes in PFC activity and metabolism might underlie working memory improvements. For instance, Klingberg, Forssberg, and Westerberg (2002) measured brain activity in 14 subjects age 9 to 18 years while they performed a spatial delayed recognition task under low versus high memory load conditions. They reported activation in superior and middle frontal regions, as well as regions of the parietal lobe, that increased with age and working memory capacity. Similarly, Kwon, Reiss, and Menon (2002) reported age-related increases in PFC activation associated with visuospatial 2-back performance in 23 subjects age 7 to 22 years. Despite these intriguing reports, it remains the case that few studies have comprehensively examined the normative development of executive working memory processes in larger samples of individuals spanning the age range from early adolescence to young adulthood.

One expectation is that adolescents will demonstrate a progressive ability to integrate multiple sources of information on tasks requiring memory, cross-temporal response selection, and strategic organization. To test this hypothesis, our lab is utilizing a battery of tasks, some experimental and some borrowed from clinical neuropsychology, that we have ordered based on the level of multitasking (low, moderate, and high) required for each task (Luciana, Conklin, Hooper, & Yarger, 2005). Our ordering scheme is based on the empirical literature on working memory and cognitive control, as described in the previous section. Much of the description that follows is based on Luciana et al., 2005.

At the low end of the hierarchy is a passive recognition memory task, implemented for discriminant validity purposes, that requires individuals to encode and then recognize neutrally posed human faces after a brief delay interval. Next is a spatial delayed response task (Goldman-Rakic, 1987a) that is known to be associated with PFC activation in primates. Spatial memory span,

using the Corsi Block Task (Milner, 1971), was implemented next, because its backward response condition requires the maintenance plus manipulation of multiple spatial locations in memory. Finally, a computerized self-ordered search task is used to assess strategic self-monitoring in the context of visuospatial memory (Owen, Downes, Sahakian, Polkey, & Robbins, 1990; Owen, Doyon, Petrides, & Evans, 1996; Owen, Evans, & Petrides, 1996). Because executive control processes have been recently linked with fluid aspects of global intellectual function (IQ; Gray, Chabris, & Braver, 2003), IQ is also measured.

One initial hypothesis was that adolescents would succeed at passively recognizing information before they would succeed at recall-guided action. Indeed, it was expected that recognition memory would not show pronounced development during adolescence, consistent with findings from other studies (Luciana & Nelson, 1998; Nelson, 1995). In the domain of recall, execution of an action based on the recall of a single unit of information was hypothesized to stabilize in development prior to the execution of actions based on the recall of multiple units. Recall-guided actions that occur in a fixed sequence would precede actions that must be recalled and then reordered. Finally, recall-guided reordering of information would precede the ability to strategically self-organize responses to multiple units of information in a more flexible manner.

It was expected that IQ would be unrelated to these developmental trends. Thus, consistent with our view of executive working memory as a dimensional hierarchical construct, it was expected that in the domain of nonverbal working memory, passive recognition memory would cease to show pronounced age-related change prior to adolescence, followed, in a staggered fashion, by the more active recall-guided tasks of simple delayed response, forward spatial memory span, backward spatial memory span, and strategic spatial self-organization.

This study relied on a convenience sample of families whose contact information is maintained by our Institute of Child Development in an ongoing research database. A medical and demographic history was obtained from parents through use of a structured interview questionnaire. Participants ranged in age from 9 to 17 years ($M = 12.51$, $SD = 2.93$ years), roughly balanced by gender. The sample is largely Caucasian and middle to upper middle class based on levels of parental education and family income. General intelligence, as estimated from selected subtasks of the age-appropriate version of the Wechsler Intelligence Scales (Wechsler, 1991, 1997), indicates that the sample is above average in IQ. Equal numbers of participants have

not been studied in all age groups between 9 and 17, but all age groups have been sampled.

Our findings indicate that executive aspects of spatial working memory are developing well into the adolescent period in a dimensional hierarchical manner independent of general intellect. When recall must be used to strategically organize behavior (self-ordered search), development is evident up to the age of 16 years and remains stable through the age range studied. Self-ordered search errors for 6 to 8 items were converted into z-scores and are graphed in Figure 7.4 to illustrate this trend. De Luca et al. (2003) recently demonstrated that performance on the CANTAB's self-ordered search task is maximal (based on error scores) in 15- to 19- and 20- to 29-year-olds, as these groups perform better than 8- to 10-, 11- to 14-, and 50- to 64-year-olds. Their 20- to 29-year-old group also achieved the best strategy scores, which were significantly better than those produced by 8- to 10- and 50- to 64-year-olds. Similarly, De Luca et al. showed that on the Tower of London, 15- to 19- and 20- to 29-year-olds achieved significantly more perfect solutions than did 8- to 14-year-olds.

A task that required relatively simplified spatial working memory demands, the spatial delayed response task, did not index developmental changes in our study after ages 11 to 12. Recognition memory for nonverbal (face) stimuli appears to mature early, as performance did not significantly change during this broad developmental period. This pattern suggests that this ability stabilizes prior to age 9 years, consistent with what has been reported for other

forms of nonverbal recognition memory (Luciana & Nelson, 1998, 2002). Spatial memory span showed an intermediate pattern, with development continuing up to age 13. Thus, when nonverbal working memory is deconstructed into its relevant task demands, an orderly developmental progression in skill appears evident, and this progression is paralleled by findings from the neurodevelopment literature. These findings suggest two major implications, one related to the maturation of distinct PFC regions and the other related to the organization of the prefrontal cortex by level of processing.

Maturation of Distinct Lateral Prefrontal Cortex Regions

Recognition memory has been traditionally thought to be reliant on temporal lobe memory systems regardless of the type of information that must be processed (Nelson, 1995). However, recent studies indicate that, depending on the paradigm used, recognition memory might also recruit the PFC (Petrides, 1995). Petrides found that the ventrolateral frontal cortex was activated when subjects were required to make active judgments about the familiarity of recently presented visual stimuli. The observed activation was enhanced relative to what was observed when either novel or familiar stimuli were presented and encoded in the absence of mnemonic judgments. Thus, the maintenance component of delayed-match-to-sample tasks might depend partly on the ventrolateral prefrontal cortex. However, the working memory and executive demands of the face recognition task used in our study are low (see Luciana et al., 2005). Although a delay interval was introduced, specific *responses* did not have to be held in mind over that delay. Instead, the major task was to correctly encode stimuli as they are presented, because a range of possible alternatives, including the correct one, could be reviewed prior to retrieval and response selection.

The spatial delayed response task appears to more distinctly depend on the dorsolateral prefrontal cortex in non-human primates (Goldman-Rakic, 1987a). A network of structures including the inferior parietal lobe, the dorsomedial thalamus, the caudate nucleus, the superior colliculus, and the hippocampus promotes successful task performance (Selemon & Goldman-Rakic, 1988). In particular, the inferior parietal lobe has the role of mapping the coordinates of spatially relevant targets in extrapersonal space, and the dorsolateral prefrontal cortex not only maintains these coordinates over time but relays this information to motor output regions so that a response can be executed at the appropriate time. Unlike recognition memory tasks,

Figure 7.4 Values represent z-scores of summed forgetting errors for 6 to 8 item searches on CANTAB's spatial self-ordered search task in healthy individuals between the ages of 9 and 17 years. The ability to self-order searches of this type, perceived as relatively difficult by healthy young adults, appears to rapidly accelerate between the ages of 10 and 14 years and to plateau by age 17.

this task requires accurate encoding of the target's location in space, formulating a response based on this location, holding this recall-guided response information in mind over a delay interval, then carefully executing the response. Performance accuracy is measured with precision, at the pixel level. However, despite the animal literature, it is not possible to know whether this visuomanual task activates the PFC in humans and, if so, which subregion is critical for performance. This uncertainty is due to technical limitations imposed by neuroimaging. The task cannot be administered without a substantial modification that biases it in favor of a demand for recognition versus recall. One commonly implemented paradigm is for human subjects to view a spatial target, after which a delay interval is imposed. Then a second screen appears, consisting of the previously seen target as well as a number of distractors. One of the items on the second screen is highlighted, and the participant must indicate with a yes/no response whether the highlighted item is the same as the one he or she previously saw (Belger et al., 1998; Jonides et al., 1993). Thus, the mnemonic-motor integration that is demanded during the delay interval when the task is administered under visuomanual response conditions is absent. Whether spatial maintenance measured in this manner activates the DLPFC is currently debated. Some studies do not find PFC activation but instead report that the task relies on a network of structures in the posterior right hemisphere, including the inferior parietal lobe.

Despite the motoric demands that distinguish it from most similar tasks used in neuroimaging contexts, our spatial delayed response task is largely a maintenance-only (D'Esposito & Postle, 1999) task. One stimulus must be held in mind over a delay interval. As the delay increases, there is an increasing endogenous demand on inhibitory control mechanisms to resist distractions. The task should, as the animal literature suggests, recruit executive processing that is PFC-mediated, particularly as delay intervals become longer. However, it may be that the task is more strongly associated with ventrolateral (versus dorsolateral) PFC function in humans as opposed to animals.

PET has been used to demonstrate that forward spatial memory span activates a network of right hemisphere structures, including the ventrolateral PFC (Owen, Evans, et al., 1996). In contrast, tasks that require backward memory span, whether the stimuli are verbal or spatial, appear to activate areas of the ventrolateral but also dorsolateral PFC (Owen, 1997). We found similar age-related influences on forward and backward span in our study, which was unexpected. It may be the case that finer task-related distinctions would have been observed had we had a large

enough sample to attempt to distinguish performance among each age group from 9 to 17 years.

The most demanding purely cognitive task in our battery is the spatial self-ordered search task, which requires response selection, memory, continuous updating of information, and a high degree of executive control. It also demands self-monitoring and formulation of a strategy, a task variable that has been shown to be specifically impaired in neurological patients with frontal, but not temporal, lobe lesions (Owen, Morris, et al., 1996).

The development of these skills, when demanded simultaneously, shows a protracted and extended course up to the age of 16 years. Our sample of 16- to 17-year-olds did not differ from slightly older (18- to 20-year-old) adults (Luciana et al., 2005), consistent with findings from a recent study where 15- to 19-year-olds were reported to perform similarly to 20- to 29-year-olds on this task (De Luca et al., 2003). As this type of task strongly recruits activity in the middorsolateral prefrontal cortex based on recent neuroimaging (PET; A. C. H. Lee et al., 2000; Owen, Doyon, et al., 1996; Owen, Evans, et al., 1996) and lesion (Petrides, 2000) studies, we and others have suggested that executive control is primarily mediated by this region. Overall, the pattern of findings that we observed suggests that different PFC regions reach functional maturity at different rates, with the ventrolateral region maturing prior to the dorsolateral region, which is responsible for the highest level of executive control over information processing.

Implications for Prefrontal Cortex Organization According to Processing Demand

The data presented here support behavioral development of working memory functions within the spatial domain according to level of processing demand. If the PFC is unified to promote working memory processes regardless of stimulus domain, then similar developmental trajectories should be evident for verbal and spatial tasks that have equivalent processing demands. However, if level of processing is distinctly modulated by different PFC regions, then tasks may dissociate across stimulus modalities according to their demands for executive control. These hypotheses remain to be tested in combined behavioral and neuroimaging protocols.

Cognition-Emotion Interactions and Development of the Ventromedial Prefrontal Cortex

These findings are compelling in providing evidence that the lateral PFC continues to mature well into adolescence, corresponding to the time period when myelination is

progressively increasing and synaptic efficiency is improving due to the pruning back of unused connections. However, to some extent, the tasks that have just been described are somewhat “dry” and seemingly removed from the type of information processing that is demanded in daily social contexts. Such tasks have been described in terms of “cool” versus “hot” measures of cognition (Metcalfe, 2000). Hot measures of cognition include those tasks that have been described in this chapter in relation to the ventral/orbital region of the PFC.

It is only relatively recently that the functional development of the VMPFC has been investigated. Some studies (reviewed by Happeney et al., 2004) have demonstrated decreases in resistance to extinction in preschool-age children, but this phenomenon has not been thoroughly investigated. On the other hand, age-related improvements in reversal learning capacity have been described for a number of years, with an intriguing suggestion of gender differences in the rate of development of this behavior (Overman, Bachevalier, Schuhmann, & Ryan, 1996; Reavis & Overman, 2001). Infant boys (younger than 30 months) outperform girls, a finding that is consistent with evidence for developmental differences in gonadal hormones in the orbitofrontal region that might limit females’ rate of learning on such tasks (Clark & Goldman-Rakic, 1989).

As mentioned earlier, the Iowa Gambling Task and similar measures are currently viewed as state of the art in VMPFC assessment because they add a strong motivational element to an otherwise complex information-processing task (see Figure 7.3). On each trial of the IGT, the test taker must select from one of four decks of cards, presented on a computer screen. After each selection, feedback is provided indicating that a certain amount of money has been won and, perhaps, also that a certain amount has been lost. Participants are instructed to attempt to win as much money as possible. Two of the decks, termed “disadvantageous decks,” yield high immediate payoffs and are therefore quite compelling. However, over the course of trials, these decks will ultimately result in net loss versus gain. The other two decks, termed “advantageous decks,” yield smaller immediate payoffs and can seem less compelling in the short term. However, over successive trials, choosing from these decks leads to net gains versus losses. The overall number of advantageous choices minus the number of disadvantageous choices is a measure of decision making that is directed by an appreciation of future, versus immediate, consequences. Although it has not been discussed in terms of its cognitive control or multitasking requirements, the IGT requires a lot of information to be simultaneously processed and utilized to direct future actions.

Kerr and Zelazo (2004) developed an analogue of the IGT that can be reliably administered to preschool-age children. This task utilizes two cards instead of four. Four-year-olds were found to make more advantageous decisions than 3-year-olds. Using a version of the task more similar to the original, Garon and Moore (2004) reported superior performance in 6-year-olds as compared to younger (3- to 4-year-old) children. Intriguingly, there is some suggestion in these studies of very young children that males exhibit superior performance on the task, a phenomenon that has also been reported in adults (Reavis & Overman, 2001).

IGT performance has also been compared in healthy individuals versus children and adolescents with externalizing psychopathology. Blair, Colledge, and Mitchell (2001) studied boys, ages 9 to 16 years, who had histories of behavioral difficulties and who were divided into two groups based on their scores on a measure of psychopathy. A main effect of age was reported: Older children chose more advantageously than younger children as the task progressed. Regardless of age, those with higher psychopathic tendencies chose more from disadvantageous decks, particularly later in the trial sequence. Another study (Ernst et al., 2003) examined IGT performance in 12- to 14-year-old adolescents with and without behavior disorders (ADHD or Conduct Disorder) as compared to healthy adults. No performance differences were found between healthy adolescents and healthy adults, but adolescents with and without behavioral disorders differed from one another. The IGT was administered twice to each participant, with 1 week separating the two administrations. Most of the differences between the two adolescent groups were found in the second administration. Specifically, the healthy adolescents had much higher scores in the second administration than the first, although this was not the case for the adolescents with behavior disorders.

Another recent study (Crone, Vendel, & van der Molen, 2003) examined age-related differences in performance on an analogue of the IGT (the Hungry Donkey Task) in 12- to 25-year-olds in relation to measures of cognitive and behavioral inhibition. The Hungry Donkey Task used a similar schedule of rewards and punishments as the conventional version of the IGT (Bechara et al., 1994), but rather than picking cards to win play money or to win actual money for themselves, the children were asked to open doors to find apples to feed a hungry donkey. Crone and colleagues found that Hungry Donkey Task performance was related to self-reported levels of cognitive inhibition. Protracted development of performance on the Hungry Donkey Task was also reported, in that adults (ages 18 to 25) made more advantageous choices than a group of 12- to 17-year-olds. In

addition to these reports, two labs have assessed the adolescent development of IGT performance (Hooper, Luciana, Conklin, & Yarger, 2004; Overman et al., 2004).

Overman and colleagues (2004) found steady improvement on the task from sixth grade to adulthood, with differential patterns of performance evident in males versus females. Females tended to choose cards that maximized both immediate and long-term gain. Males tended to choose cards based more exclusively on their potential for long-term gain. Our group's findings were that 14- to 17-year-olds made more advantageous choices than did younger age groups on the IGT, particularly in the last two trial blocks. However, the 14- to 17-year-olds in our study performed worse than adults who have served as control subjects in other reports (Hooper et al., 2004). We also found no relation between IGT performance and performance on other measures of PFC function, such as response inhibition and working memory. Finally, although we did not find that males outperformed females on the task, we did observe gender differences in deck preferences. Specifically, females were more likely to choose from decks that yielded infrequent punishments, regardless of the magnitude of the reward associated with a given deck.

Figure 7.5 depicts adolescents' performance on the IGT relative to that of both younger children and young adults. As is evident in the figure, the skills necessary to perform the IGT with maximal efficiency appear to be developing even after the age of 17 years. Because we have not studied adults' performance as they progress into their 20s and 30s, the upper limit of this developmental progression is not known.

Figure 7.5 Adolescents' performance on the Iowa Gambling Task illustrates a steady developmental progression in decision-making skills that appears to accelerate after the age of 17.

Overall, these are compelling findings from the standpoint of the development of multitasking skills and the development of cognition-emotion interactions. In theory, the relatively "deficient" performance of 17-year-old adolescents on the IGT could be due to the fact that the dorsolateral PFC is challenged to mediate the cognition-emotion interface and falls somewhat short due to developmental constraints on its multitasking capacities. Whether this constraint is imposed by lack of dorsolateral PFC maturation, lack of ventromedial maturation, or the connections between them is a matter for further empirical study.

Summary

The normative development of PFC-guided behaviors has been investigated through a combination of behavioral experiments, animal lesion studies, and neuroimaging investigations. These studies converge to suggest a dimensional course of PFC development. Rudimentary levels of multitasking skill emerge late in infancy, coincident with locomotor initiation. Progressively more information can be managed and appropriately acted on during the preschool period and extending into middle childhood. Most recently, it has been suggested by neuroimaging and neurobehavioral studies that adolescence may represent a critical period in PFC maturation. This may be particularly true if the PFC must juggle both cognitive and emotional task contingencies. When multitasking is demanded in the context of high emotional salience, the PFC appears unable to respond with maximal efficiency even late in the 2nd decade of life.

INDIVIDUAL DIFFERENCES AND VULNERABILITY TO PATHOLOGY

Understanding the PFC's mediation of multitasking from a dimensional perspective holds a great deal of explanatory power. For the PFC to be taxed in its ability to orchestrate behavior, the multitasking that is demanded by a situation must exceed some critical threshold. That is, *the same situational context (or behavioral task) will not necessarily recruit the same degree of PFC activity in all people at all times*. Moreover, we know from neuroimaging studies that once a task becomes too demanding, the dorsolateral PFC more or less shuts down (Callicott et al., 1999). Thus, within an individually determined situational range, defined by an activation threshold or "on" switch at the low end and by some as yet undetermined overload indicator at the high end, the PFC effortfully works to process information that presents a challenge to the individual. Next, how

neural insult or individual differences in neurochemistry might impact the PFC's processing mechanisms is considered. This discussion highlights three disorders, each of which differentially expresses (1) a developmentally mediated risk for psychopathology, (2) hypothesized dysfunction of the prefrontal cortex, and (3) neurochemical dysregulation that involves the dopamine system and its projections to the PFC, among other brain regions.

Schizophrenia: Aberrant Prefrontal Function Due to a Neurodevelopmental Lesion?

As most students of abnormal psychology are aware, Schizophrenia typically does not manifest itself until late adolescence or young adulthood (American Psychiatric Association, 1994). Its symptoms include positive indications of thought disorder, such as hallucinations or delusions, as well as deficits such as anhedonia, anergia, and an inability to form meaningful social relationships. Once symptoms begin to present themselves, behavior and the affected person's general level of function radically deteriorate. One robust finding is that individuals with Schizophrenia perform poorly on putative measures of frontal lobe function (Park & Holzmann, 1992; Perlstein, Dixit, Carter, Noll, & Cohen, 2003). The disorder is sometimes, but only rarely, seen in children. However, recent theories suggest that it is best conceptualized as a developmental disorder in which a static lesion that occurs before adulthood interacts with normal maturational events to produce later signs of the illness (see review by Lewis & Levitt, 2002). The notion that the pathological events that cause the illness are present much earlier than its presenting symptoms was suggested by Bleuler and Kraepelin over a century ago (described by Marenco & Weinberger, 2000), an idea that was elaborated on by Weinberger in the 1980s. Weinberger (1986, 1987) postulated that an early developmental lesion, perhaps occurring prenatally, was responsible for the disorder in conjunction with environmental triggers and other genetic liabilities. According to Weinberger's original model, the lesion impacted the dorsolateral prefrontal cortex and altered prefrontal dopamine transmission during adolescence, which was regarded as a critical period during which a juxtaposition of brain maturational events, environmental stress, and a demand for the PFC to assume control over behavior led to the manifestation of the disorder. Thus, in this diathesis-stress model, the PFC dysfunction that characterizes Schizophrenia is viewed as a sleeper effect, present from birth but dormant early in development and emergent only when the PFC reaches functional maturity. Other neurodevelopmental

models suggest that Schizophrenia manifests itself due to later developmental events, such as failures of synaptic pruning that are specific to adolescence (reviewed by Lewis & Levitt, 2002). The neurodevelopmental hypothesis is not fully accepted but is supported by several lines of evidence, including an increased incidence of perinatal complications in people later diagnosed with Schizophrenia; the presence of soft neurological signs and other minor physical anomalies in subsets of individuals with the disease; evidence of intellectual, motor, and behavioral dysfunction prior to diagnosis; the presence of structural brain abnormalities that remain stable over time; and a course of illness that is contrary to what would be expected in a degenerative disease (Lewis & Levitt, 2002; Marenco & Weinberger, 2000). Autopsy studies of affected individuals' brains reveal evidence of migrational errors in the PFC that impact white matter development (Akbarian et al., 1993) as well as disrupted patterns of cortical connectivity (Selemon & Goldman-Rakic, 1999). In addition, minor physical anomalies, particularly deviations in craniofacial morphology (Lane, Larkin, Waddington, & O'Callaghan, 1996; Lane et al., 1997), differentiate schizophrenics from age-matched controls, suggesting that a teratogenic process that impacts development of the ectoderm layer in the developing fetus is associated with the disorder. One classic study by Walker and colleagues (Walker, Savoie, & Davis, 1994) involved the retrospective rating of home videos recorded by parents of schizophrenic children and nonaffected children, including siblings. Raters, unaware of each individual's adult diagnostic classification, viewed the videos and rated them for the presence or absence of motor idiosyncrasies and other neurological abnormalities. They were able to successfully discriminate children who would later manifest Schizophrenia from unaffected children, including siblings, suggesting that Schizophrenia might manifest itself during childhood in the form of subtle motor abnormalities. Motor abnormalities were particularly evident prior to 2 years of age. In Walker et al.'s (1994) model, these abnormalities were linked with dysfunction in the basal ganglia and a lack of cortical (prefrontal) control over subcortical (motor) processes. Neuropsychological symptoms were hypothesized to appear later, when the PFC becomes more important for cognitive, as opposed to motor, control over behavior.

Perceived stress triggers more frequent episodes of the disease and renders chronic sufferers more susceptible to impairment. As suggested by this review, individuals with the biological diathesis for Schizophrenia might have a low threshold to experience PFC overload as they are bombarded by stimuli from the environment. Thus, the individ-

ual is taxed by an information load that is significantly less in magnitude than what would challenge a healthy person, ultimately leading to PFC hypoactivation, which has been observed in PET and neuroimaging studies (Perlstein et al., 2003). The interesting aspect of the disorder, from a developmental perspective, concerns the application of normative principles of PFC development to the time course of the illness. If the model outlined in this chapter is correct regarding the normative course of PFC development, then Schizophrenia manifests itself at a point when the PFC assumes maximal control over cognition-emotion integration. If the neural processes underlying this developmental milestone can be identified in healthy adolescents, they might suggest areas of deviated function in the schizophrenic brain.

Phenylketonuria: Chronic Deviation in Prefrontal Dopamine Activity?

In contrast to Schizophrenia, another neurodevelopmental disorder that has been linked to deficits in PFC dopamine activity is phenylketonuria (PKU). Individuals with PKU suffer from a genetic lack of the enzyme phenylalanine hydroxylase (PAH); as a consequence, they are unable to metabolize phenylalanine, a naturally occurring protein that is abundantly present in the typical human's diet. When phenylalanine levels rise, they are toxic to the developing nervous system, and profound mental retardation results. Since the disorder was first recognized, neonatal screening for PKU has become the norm in most Western countries, and treatment is instituted as soon as possible after birth. Treatment involves the dietary restriction of phenylalanine. With dietary treatment, mental retardation is averted (Williamson, Koch, Azen, & Chang, 1981). However, individuals with PKU still differ cognitively from unaffected individuals, which may be due to factors related to the manner in which phenylalanine influences neurochemistry, especially in the prefrontal cortex (Diamond, Prevor, Calender, & Druin, 1997).

Phenylalanine is involved in the synthesis of dopamine. Through the action of PAH, phenylalanine is converted in the central nervous system into tyrosine, which in turn is metabolized by tyrosine hydroxylase into dopamine (Goodwill et al., 1997; McKean & Peterson, 1970). Through several possible mechanisms, dopamine synthesis might be compromised in PKU. First, if phenylalanine is unduly restricted, as in a rigorously controlled PKU diet, then dopamine synthesis might be impaired because there is little to no phenylalanine available for conversion to tyrosine. Tyrosine is also ingested through protein-rich foods, so it

must be supplemented in PKU. However, even when phenylalanine levels are only moderately elevated, as in a restricted but not entirely efficacious diet, dopamine levels might also be decreased due to the fact that phenylalanine and tyrosine compete for transport across the blood-brain barrier (Carlson, Hyman, Bauman, & Koch, 1992; Pietz et al., 1999). If phenylalanine levels are elevated, then phenylalanine might win out in the competition for blood-to-brain transport. Once in the central nervous system, phenylalanine cannot be metabolized, and not enough tyrosine has entered the brain. Without tyrosine, dopamine is not synthesized. In theory, tyrosine depletion should impact all brain regions that use dopamine as a transmitter; however, it has been suggested that the PFC is particularly sensitive to dopamine precursor depletion (Diamond et al., 1997). If this is accurate, then individuals with treated PKU should demonstrate specific deficits in the area of executive function. Concordantly, executive function deficits have been reported in preschoolers and school-age children with PKU despite the fact that these children have IQs in the normal range. Deficits have been reported on measures of set shifting, working memory, and other aspects of higher-order problem solving (Diamond et al., 1997; Faust, Libon, & Pueschel, 1986; Pennington, van Doorninck, McCabe, & McCabe, 1985; Weglage, Pietsch, Fünders, Koch, & Ullrich, 1996; Welsh, Pennington, Ozonoff, Rouse, & McCabe, 1990; White, Nortz, Mandernach, Huntington, & Steiner, 2002). Some studies have also observed relative deficits in choice reaction times or interhemispheric transfer times (Banich, Passarotti, White, Nortz, & Steiner, 2000; Gourovitch, Craft, Dowton, Ambrose, & Sparta, 1994), suggesting that the speed of information processing is impacted in PKU. Interestingly, these deficits have been less robustly observed in adolescents and young adults with the disorder, suggesting the presence of an as yet undetermined compensatory mechanism as the PFC matures (Mazzocco et al., 1994).

When deficits are observed, they have been positively correlated with blood levels of phenylalanine (Diamond et al., 1997; Mazzocco et al., 1994; Ris, Williams, Hunt, Berry, & Leslie, 1994; Weglage et al., 1996; Welsh et al., 1990). Recently, studies have focused on the blood phenylalanine-to-tyrosine ratio as a marker of brain dopamine availability (Diamond et al., 1997). Low ratio scores have been associated with executive function deficits in several studies, one of which (Luciana, Sullivan, et al., 2001) suggests that low ratios at discrete developmental time points might confer vulnerability to later executive dysfunction.

In addition, we recently attempted a pharmacological challenge of the dopamine system in young adults with

PKU, using the dopamine antagonist haloperidol (Luciana, Hanson, & Whitley, 2003). Young adults with PKU and a group of age-matched controls completed a neurocognitive battery under the influence of haloperidol and, on a separate study day, a placebo. It was predicted that haloperidol would impair selected aspects of cognition, particularly in the realm of working memory, in both groups relative to placebo, but that the degree of impairment would be greater in the PKU sample. This prediction was only partially supported, although a composite measure of executive function impairment on haloperidol distinguished the PKU from the control group. Responses to haloperidol were variable within the PKU sample (e.g., 50% of that sample exhibited executive function impairment on haloperidol as compared to 25% of the control sample), leading us to speculate that other, individual difference factors might impact whether or not an individual with PKU suffers from chronic tyrosine depletion and whether such depletion, if present, specifically impacts the prefrontal cortex. Similar psychopharmacological investigations might be particularly illuminating if they could be conducted to compare the responses of children, adolescents, and young adults with the disorder.

Because dopamine neurotransmission is hypothesized to be specifically disrupted in PKU, another interesting avenue of research might be to investigate how PKU interacts with other genetic liabilities to determine the likelihood of cognitive dysfunction in a given individual. That is, we might predict that individuals who carry the VAL allele of the COMT gene would be at particularly high risk of prefrontal dopamine loss due to interactive effects of COMT genotype with PKU. To date, this association has not been investigated. Another association that could be investigated, particularly as cohorts of treated individuals with PKU reach middle and older adulthood, is the similarity between cognitive dysfunctions in PKU and those observed in other dopamine-related disorders such as Parkinson's disease.

In summary, because PKU is relatively well understood from a neurochemical perspective, its study has the potential to increase our understanding of other disorders that disrupt prefrontal function through neurochemical means. In addition, PKU is unique because it is diagnosed very shortly after birth and its effects can be observed in the context of a treatment that is applied throughout the life span.

In contrast, another disorder that has been associated with aberrant dopamine function (although not limited to the prefrontal cortex) is substance abuse. Substance abuse typically does not manifest itself until adolescence or

adulthood, depending on an individual's environment as well as genetic predisposition.

Substance Abuse: Subcortically Generated Motivational Signals Impact Higher Levels of Information Processing

Substance abuse can be understood, only in part, as a failure of cognitive control. Current models of substance use problems emphasize that all individuals (even those who do not use drugs or alcohol) vary in their sensitivities to rewarding stimuli. Rewards can be natural unconditioned reinforcers, such as food, shelter, and warmth, that an individual will approach without prior learning. Alternatively, they can be conditioned through experience, such as likes and dislikes that pertain to specific foods and specific sources of contact comfort. Whether a stimulus is rewarding (reinforcing) or not depends on the degree to which one responds to it at a neurobiological level. Stimuli that are reinforcing activate a functional circuit in the basolateral limbic forebrain. Relevant structures include the amygdala, nucleus accumbens, dorsal striatum, and ventromedial prefrontal cortex. Using dopamine as the primary transmitter, information regarding reward salience is transmitted through this circuit (Depue & Collins, 1999). The nucleus accumbens-striatal interface ultimately allows information pertaining to positive incentives to be translated into approach behavior (Depue & Collins, 1999; Mogenson et al., 1980). If a situation or stimulus is particularly compelling, activity in this circuit would be expected to be quite robust, underlying the brain's primary reward system. Achieving control over reward-stimulated approach behavior is clearly a critical need, allowing potential sources of reward to be acquired in ways that are adaptive and appropriate to the situational context.

When the reward system is overly active, it is conjectured that an intact DLPFC must exert a greater-than-normal amount of effort to subdue hedonic impulses. Alternatively, even "typical" impulses that are generated subcortically could lead to lack of behavioral control in the absence of adequate PFC function. The impulses most relevant for drug abuse initiation are hedonic signals related to positive reinforcers and/or unconditioned natural rewards. These two mechanisms might differentially characterize drug abuse early versus later in its course as a function of (1) developmental constraints and (2) the effects of drugs on neurobehavioral systems once use is initiated. Epidemiological studies (DeWit, Adlaf, Offord, & Ogborne, 2000; B. F. Grant & Dawson, 1997, 1998; McGue, Iacono, Legrand, Malone, & Elkins, 2001) suggest that initiation of drug and alco-

hol use begins early, typically during adolescence. Initial use or experimentation is not necessarily aberrant, because hedonic signals may be especially compelling during adolescence, when exploratory tendencies are high. However, the course of addictive behavior (as it emerges) will vary depending on how well one can exert control over these impulses. Appropriate levels of control will be difficult, if not impossible, to achieve if the DLPFC is not functionally mature. Moreover, as noted previously, substance abusers have been shown to perform poorly on measures of VMPFC function, such as the Iowa Gambling Task. Therefore, the general trajectory of PFC maturation in adolescence, as well as sources of individual variation in this trajectory, have important ramifications for drug use initiation and maintenance.

The study of PFC development informs the study of drug abuse in two major ways. First, an understanding of the PFC's capacity for information integration and control during adolescence is important in identifying individuals who might be vulnerable to the initiation of drug use. The second area of interest concerns the impact of drug use, once initiated, on PFC-guided networks. Individuals with deficient PFC function may be most vulnerable to drug use initiation, but it may also be the case that continued use of drugs is detrimental to PFC development (e.g., Ornstein et al., 2000; Sullivan, Fama, Rosenbloom, & Pfefferbaum, 2002) due to the long-term effects of use on synaptic connections.

If our and others' laboratory data are correct regarding the maturational trajectory of PFC function, then drug use is initiated at a time when the PFC is still actively developing. Indeed, periods of pronounced functional development in a normative sample may represent periods of maximal vulnerability if drugs are used at these times.

Summary

These three disorders (Schizophrenia, phenylketonuria, and substance abuse) have several superficial features in common. Each has been associated with prefrontal dysfunction at a behavioral level and with deviations in dopamine system neurotransmission. In the case of Schizophrenia, an early lesion process critically impacts the development of cortical circuitry but is not evident until the environment becomes sufficiently stressful and that circuitry is called on to assume control over behavior. In phenylketonuria, it may be the case that affected individuals suffer from chronic tyrosine depletion, secondary to a primary deficit in phenylalanine metabolism. This depletion acutely affects neural function as the cortex is developing and may be specific to the prefrontal cortex at different points in development. Finally, although sub-

stance abusers frequently exhibit deficits in behavioral control that could be attributed to deficient prefrontal function, they may be primarily characterized by an overactive approach or reward system that is difficult to restrain in the presence of reinforcing stimuli. Thus, the PFC must work in an increasingly effortful manner to keep behavior in an adaptive balance. This equilibrium can be upset by a number of processes occurring at various developmental time points.

FUTURE DIRECTIONS

The work surveyed here pertaining to the development of prefrontally guided cognitive functions in healthy children and implications of these developmental processes for psychopathology raises a number of interesting questions and ideas for future study. Some of these issues pertain to methodology; others relate more strongly to the types of questions that might guide future investigations in light of current knowledge.

On the methodological front, there has been an emphasis in the literature to date on deriving conclusions about PFC development from behavioral tasks that have been linked in adult studies to this region of the brain. However, we cannot conclude that because a task recruits PFC function in adults, it will necessarily recruit the same regions or recruit activity of the same magnitude in children and adolescents (Bunge et al., 2002; Casey, Giedd, & Thomas, 2000). Neuroimaging technology allows us to examine this issue directly in the behaving developing brain. Thus, future research should emphasize studies that combine neurobehavioral assessments with measures of functional neuroimaging.

Related to this idea, current work strongly suggests that the PFC undergoes continued structural refinement in the adolescent period (Sowell, Delis, et al., 2001; Sowell, Thompson, et al., 2001). However, only a handful of studies have attempted to address how these structural changes relate meaningfully to behavioral changes that are also prominent during this time (Klingberg et al., 2002; Kwon et al., 2002; Sowell, Delis, et al., 2001), and a need for studies of this type has been identified by others (Paus et al., 2001). In isolation, each of these reports has suggested intriguing associations between patterns of white matter development and improvement of performance on working memory or cognitive control tasks (Klingberg et al., 2002; Kwon et al., 2002) or associations between patterns of gray matter decline and mnemonic improvement on tasks that have been loosely linked to the PFC (Sowell, Delis et al., 2001). There is a sense in evaluating

this literature that tasks have been selected less carefully than they might be given the vast amount of knowledge that has been gained from large-scale behavioral studies of prefrontal development (e.g., see Welsh et al., 1991). To the extent that behavioral investigations can suggest specific tasks that target processes of interest, these tasks can be brought into neuroimaging paradigms and subjected to intense scrutiny. For example, measures of response inhibition (Bunge et al., 2002) and strategic self-monitoring (De Luca et al., 2003; Luciana et al., 2005) have been found to continuously develop during adolescence, and these could be examined in relation to white matter development in dorsolateral prefrontal regions. Similarly, studies incorporating measures such as the Iowa Gambling Task (Hooper et al., 2004; Overman et al., 2004) or its cousin, the Hungry Donkey Task (Crone et al., 2003), suggest that adolescents continue to improve in their capacities for cognition-emotion integration into their 20s. These tasks could be examined in relation to synaptic integrity in the ventromedial prefrontal cortex.

Refined investigations of structure-function correlations seem destined to rely on small study samples given the current prohibitive financial and time costs of conducting neuroimaging investigations. However, one other trend that is being encouraged on a national level is for researchers to combine their resources and data sets to create large public databases (Van Horn, Grafton, Rockmore, & Gazzaniga, 2004) that can then be queried by independent investigators to consider broader issues. It might be possible to use data generated across sites to more comprehensively investigate age-related trends in the development of basic neurofunctional aspects of PFC development, particularly as investigators agree on tasks to incorporate in their assessment paradigms.

It is not sufficient, however, to rely on cross-sectional comparisons, as many investigators have done, to inform developmental theories. Prospective within-subject designs are those that have the maximal capacity to address developmental questions (see Giedd et al., 1999, for a notable example). If prospective studies can be designed that utilize multimethod approaches (e.g., combinations of behavioral, neuroimaging, and molecular genetic assessments), then growth curve models can be derived to segregate multiple sources of influence over behavior in the context of typical development. Such studies would also allow for the examination of transitions from healthy to disordered patterns of behavior within the same individuals.

Now that so much knowledge has come to the forefront regarding normative trends in PFC development, studies of

high-risk samples and children with diagnosed psychopathology are critical to truly understand how the PFC controls behavior from a multidimensional interactive perspective. One dimension of interest obviously concerns age and how and when high-level cognition emerges over time. Another dimension, though, concerns the continuum from typical to maladaptive levels of function. Clinical investigations in combination with the knowledge gained from neuroscience seem to strongly suggest that these two dimensions might interact. That is, there are vulnerable periods in the course of the normal staging of brain development when synaptic architecture is vulnerable to exogenous but also intrinsic sources of adverse influence. As described herein, these vulnerable periods include the prenatal period (when neurons are forming and migrating to targeted destinations in the cortex), early infancy (when synaptogenesis is most exuberant), and adolescence (when synaptic pruning and white matter development further refine synaptic architecture, decreasing the amount of subsequent plasticity that is possible).

Clinical descriptions also reinforce that certain forms of psychopathology are more likely to manifest themselves at some points in development rather than others. For example, according to the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994), symptoms of ADHD must manifest themselves before the age of 7 years. Schizophrenia, in contrast, is rarely seen during childhood but has a typical age of onset in adolescence or young adulthood. Affective disorders, at least in forms that are similar to what is typically seen in an adult sufferer, emerge most often postpuberty, as does substance abuse. These lines of reasoning suggest that we should focus alternatively on the toddler/preschool but also adolescent periods and the changes that are normative within these time spans to identify which processes go awry in the context of specific disorders and exactly when in relation to the expected normative developmental trajectory these processes are maximally impacted.

More refined investigations of healthy and especially high-risk children and adolescents therefore represent one critical future direction in clinical cognitive neuroscientific investigations.

The emphasis on the prefrontal cortex as a heterogeneous structure that interacts substantially with subcortical brain regions (such as the amygdala), with the anterior cingulate cortex, and with midbrain neurotransmitter regions also indicates that developmental cognitive neuroscience is at a turning point. While most investigators have focused on studying functions that are mediated by the dor-

solateral prefrontal cortex (i.e., measures of cool cognition), current studies of the ventromedial prefrontal cortex and its role in decision making that is both nonsocial and also socially mediated should inspire us to target this region and so-called hot measures of executive cognition as active topics of investigation. Thus, developmental neuroscience may be at a nexus point, ready to intertwine with the emerging fields of affective and social cognitive neuroscience. For example, some paradigms that have been recently examined in social neuroscientific investigations concern how social cooperation develops between interacting partners (Rilling et al., 2002). There is an intriguing suggestion that such processes activate anterior cingulate but also ventral prefrontal regions. Because social cooperation is so critically important in the context of peer relations, studies of how it emerges and how it is mediated in adolescence would be particularly interesting.

Current interest in social cognitive neuroscience reinforces the notion that experience broadly defined interacts with more purely biological mechanisms to structure behavior. Specifically, executive control may be impacted by sociodemographic variables, by cultural factors, or by interactions between genetic liabilities and rearing conditions. Thus, future prospective studies of high-risk samples should ideally incorporate individuals with a diversity of experience to capture how these sources of influence interact with the other mechanisms described here.

CONCLUSIONS

The cognitive neuroscience of prefrontal development began in a rather unsophisticated way, with several notable case reports that were conveyed to the medical community. These reports gave way to the development of animal models of brain-behavior relations and extensions of relevant findings to human clinical and experimental neuropsychology. Our current knowledge regarding the manner in which the PFC mediates behavior is greatly enhanced by neuroimaging studies, but even these rely heavily on the foundation of experimental neuropsychology, through which behavioral tasks were creatively developed to assess working memory, inhibitory control, and set shifting.

Currently, the focus is on a reformulated theory of PFC function that is organized around cognitive control, defined by at least one researcher as the ability to flexibly modulate behavior to attain goals. The development of cognitive control was first studied by Piaget (1936), although he didn't

frame his discussions of object permanence in that way. Using Piagetian tasks, it has been demonstrated that abilities dependent on the PFC later in life emerge in the infancy period. From that period onward, they continue to develop in a dimensional fashion, allowing increasingly complex pieces of information to be manipulated, monitored, and otherwise organized. This pattern of behavioral development has a parallel in brain development. Although the brain's gross structural features are present at birth, the genesis and refinement of cortical circuitry continues throughout childhood and into adolescence, culminating with the elimination of excess synapses and the continued development of white matter, including myelin. These refinements, also dimensional in their emergence, parallel what is observed in behavior (Luciana, 2002).

Typically, cognitive control has been studied using measures of working memory or behavioral inhibition. It is suggested here that control culminates with the PFC's increasing capacity to integrate and respond to cognitive as well as motivational signals that are communicated from the rest of the brain. One task that has been used in only a handful of developmental studies to date, the Iowa Gambling Task, appears to index this high demand for cognition-emotion integration. Data from our laboratory at the University of Minnesota suggest that whereas complex working memory and inhibitory control processes asymptote late in the 2nd decade of life, the processes recruited by the IGT are continuing to develop up to the age of 20 and perhaps beyond. Further investigations of how the PFC integrates emotion and cognition will be important in defining the upper limits of its development, and it is suggested that this area of inquiry is the wave of the future in developmental neuroscientific research.

Because the PFC continues to develop for the first 20-some years of the average person's life, it may be particularly vulnerable to pathological processes and events, including those that are intrinsic to the individual in terms of his or her neural development, genetics, or prenatal environment (e.g., Schizophrenia or phenylketonuria). Aberrations in other areas of the brain, such as the limbic-motor interface, as seen in substance abuse, would also be expected to have a ripple effect on PFC function. Finally, although this literature was not covered here, adverse experience, in the form of neglect, maltreatment, or socioeconomic disadvantage, has been linked to attentional dysfunction and executive impairments (Beers & DeBellis, 2002). The mechanism through which such events alter PFC function could be due to effects on developing synaptic architecture, particularly if those events occur in the

time span between birth and age 5, when synaptogenesis is particularly exuberant.

It was proposed here that the PFC has a finite capacity for information integration, particularly when that integration requires control over strong motivational impulses; if that capacity is taxed through intrinsic or extrinsic stressors, executive dysfunction will result and will be observed as a failure of behavioral regulation. One challenge for developmental cognitive neuroscientists is to understand how the PFC's optimal reaction range is defined in healthy individuals between childhood and adulthood and how capacity limitations are differentially expressed in psychopathology. A multimethod approach that incorporates neuroimaging, molecular genetics, and neurobehavioral observation holds a great deal of promise in addressing this challenge in future studies.

This chapter explores the utility of neuropsychological conceptualizations of developmental psychopathology. Simply put, the field of neuropsychology is concerned with understanding brain-behavior relations. Although this field is over 200 years old, through most of its history it has been focused on understanding brain-behavior relations in mature humans and other animals mainly by examining the effects of acquired lesions. The application of a neuropsychological approach to understanding disorders of development, especially developmental psychopathology, is a relatively recent phenomenon. With a few exceptions (Orton, 1925), most of this work has been done in the past 40 years (see Benton, 1974, for a brief review of some early work in this field).

It is important to appreciate how much has changed in those 40-odd years. In the mid-1960s, few psychopathologies were regarded as brain disorders, partly because the dominant psychoanalytic and behaviorist paradigms emphasized environmental etiologies and partly because the methods for measuring brain structure and function were

so rudimentary. A strict dualistic distinction was often drawn between “organic” and “functional” disorders, with most psychiatric disorders regarded as functional. Thus, findings that challenged these views, such as evidence for heritability of disorders like Schizophrenia (Gottesman & Shields, 1976), were surprising and controversial. Neuropsychologists were critical to overturning the dominant environmental/functional view of psychopathology. They had already developed test batteries with proven sensitivity to the presence, lateralization, and localization of acquired brain damage (e.g., Reitan & Davison, 1974). When these batteries were then used with patients with psychiatric disorders, notably Schizophrenia, it became clear that several diagnoses had correlated neuropsychological dysfunction (e.g., Heaton, Baade, & Johnson, 1978), and could be thought of as brain disorders.

Behavioral methods for evaluating neuropsychological functions in children began to be developed around the same time. One impetus was the clinical need to measure the effects of childhood neurological disorders, such as

focal lesions, closed head injuries, and seizures. This work led to the emergence of the field of child clinical neuropsychology. It was soon reported that childhood brain damage was associated with psychopathology (Shaffer, 1973). Rutter (1977), using epidemiological data from the Isle of Wight studies, demonstrated that children with brain damage had a rate of emotional disturbance (34.3%) almost 6 times higher than the rate (6.6%) found in healthy controls and 3 times higher than the rate (11.5%) found in children with nonneurological physical disorders. So brain damage in childhood impaired not only cognitive development but emotional and behavioral development as well. Moreover, the association between psychopathology and brain dysfunction was found to run in the opposite direction. When neuropsychological batteries appropriate for children were applied to childhood psychiatric disorders, such as Autism and Attention-Deficit/Hyperactivity Disorder (ADHD), neuropsychological deficits were found. These batteries were also applied to childhood genetic syndromes like Turner's syndrome and early treated phenylketonuria, and particular patterns of deficits were found. The finding that somewhat distinct neuropsychological phenotypes were characteristic of *both* behaviorally and etiologically defined disorders contributed to the view that all these disorders had a neurodevelopmental origin and could be explained by the same paradigm.

Around the same time, the field of developmental neuropsychology began to emerge to address fundamental questions about the origins of the brain-behavior relations found in adults: Is there innate or progressive left hemisphere lateralization of language function (Lenneberg, 1967; Segalowitz & Gruber, 1977)? Is the young brain more plastic after brain damage than the mature brain (Goldman-Rakic, Isseroff, Schwartz, & Bugbee, 1983; Kennard, 1940)? How does localization of function emerge in development, and how plastic are these localizations (Neville, 1977)? Obviously, contributions from child clinical and developmental neuropsychology are mutually informative. The overall goal is to explain both typical and atypical behavioral development using the same paradigm. This is the goal of the relatively new field of developmental cognitive neuroscience, which has its roots in the earlier work described here, but which has recently shown dramatic growth, partly because of the advent of new technologies.

In sum, in a scant 40 years, the neuropsychological approach to understanding developmental psychopathological disorders has evolved considerably, as the work reviewed here demonstrates. The neuropsychological approach is no longer new and has been applied to explain the manifestations and potential underlying mechanisms of many differ-

ent childhood disorders. It is now time to take a critical look at how this model has proven useful and, when it has failed, what we have learned from its limitations. The neuropsychological model holds great promise for improving our understanding of multiple aspects of developmental psychopathology, as well as enhancing our knowledge of typical development. It may be useful for refining diagnosis, better predicting prognosis, and matching specific treatments to specific subtypes or profiles within a more broadly defined condition. On the other hand, rapid technological and scientific advances in fields as diverse as genetics, imaging, and connectionist modeling have led to postmodularity conceptualizations of the brain that may limit the utility of certain basic tenets of the neuropsychological perspective on developmental psychopathology.

This chapter reviews the multilevel model for analyzing developmental psychopathology laid out in the first edition of these volumes (Pennington & Welsh, 1995) and further developed in Pennington (2002). Four broad levels of analysis are discussed: etiology, brain mechanisms, neuropsychology, and behavior. Next, we focus on the neuropsychological level of analysis and its promise of providing a bridge between brain and behavior, identifying mechanisms that may be closer to and more consistent with biology than are symptoms themselves. In the third section, we examine two forms of developmental psychopathology, Autism Spectrum Disorders and Posttraumatic Stress Disorder, applying a neuroscientific perspective. Exploring these very different disorders provides a rigorous test of the neuropsychological model. After this, limitations of the neuropsychological model and ways it may not live up to its promises are discussed. Implications for future research conclude the chapter.

THE NEUROSCIENTIFIC PERSPECTIVE

In our model of developmental psychopathology (Pennington, 2002), there are four levels of analysis: the *etiological* level that examines genetic and environmental influences that heighten the risk of psychopathology, the *brain mechanisms* that these etiologies act on, the *neuropsychological processes* that are in turn disrupted by alterations in brain development, and the *symptoms* or behavioral phenotypes that are the final product of the three preceding levels. A basic tenet of multilevel analytic frameworks is that psychopathology cannot be reduced to any one level (Cicchetti & Dawson, 2002; Nelson et al., 2002). When the field of developmental psychopathology was relatively

new, much work was invested in understanding the symptom level, the specific behaviors or signs associated with specific conditions. Diagnostic taxonomies struggled to delineate symptoms that were reliably associated with a disorder and that distinguished it from other disorders. Although this work was absolutely necessary, it was not sufficient for the maturing field of developmental psychopathology, leaving many questions about causes, mechanisms, and, ultimately, treatments unanswered. Many interventions are developed from theories of causation, highlighting the importance of an understanding of underlying mechanisms. Furthermore, apparent developmental discontinuities or dissociations at the symptom level of analysis may be clarified at deeper levels of analysis. One of the basic principles fundamental to this chapter is that recent contributions from etiological, brain, and neuropsychological research have significantly matured the field of developmental psychopathology. This chapter is concerned primarily with the third level of analysis in this model, the neuropsychological level, but processes at different levels are interactive and reciprocal and so it is essential that we consider all levels.

Pennington's (2002) model chose four levels of analysis; this heuristic has proven quite useful, as we hope to illustrate in this chapter, but it remains to be seen whether four levels will be sufficient to capture the variability within and across developmental psychopathology. As our understanding of the brain improves with new innovations in technology, it may become clear that the neural level of analysis needs to be further subdivided into anatomical and chemical functional units, to take just one example. For now, we illuminate the four levels originally postulated by Pennington (1991, 2002) but return to the issue of this model's limits later in the chapter.

We propose that this four-level heuristic is valuable for understanding all developmental psychopathologies, not just those with robust evidence of biological etiology or brain involvement. Indeed, it is a basic premise of our model that the manifestations of all developmental psychopathologies are mediated by brain processes. As such, all require some understanding of the neuropsychological processes that bridge the brain and behavior levels of analysis. Even a condition with purely social-environmental (i.e., interpersonal) etiologies, with no genetic influence or neurological trauma associated with it, still alters brain development and function. Indeed, we believe it is fundamentally incorrect to distinguish between mind and brain, functional and organic, psychological and physiological, environmental and biological, nature and nurture. All

pathological processes act at some point on the brain, changing its organization and function and resulting in a pattern of atypical behavior. Thoughts, feelings, actions, indeed every aspect of behavior ultimately originate in neurons firing in particular patterns. All social influences affect brain development in some way, and all psychological processes are executed by brain mechanisms.

Two examples illustrate this close interplay between brain and behavior. It has long been observed that adults who were abused or neglected during childhood are at much greater risk for affective disorders. It is now becoming clear that traumatic early events and other early experiences alter brain development and, in this way, contribute to the development of psychopathology (Grossman et al., 2003). Persistent changes have been found in hypothalamic neurons and receptors in mice exposed to repeated maternal separations during infancy (Heim & Nemeroff, 1999). The second example comes from a treatment study of Obsessive-Compulsive Disorder (OCD) that scanned participants before and after treatment using positron emission tomography (PET). Some participants were treated with medication and others with psychotherapy. Regardless of the treatment strategy, both showed metabolic changes in the same neural systems at the outcome scan (Schwartz, Stoessel, Baxter, Martin, & Phelps, 1996). What surprised many about this study was that psychotherapy alters brain activity, and in the same way that effective medications for OCD do. These two examples clearly demonstrate that mind and brain are one and the same and that psychological constructs (i.e., psychotherapy, personality, social experiences, interpersonal risk factors) affect behavior because they affect brain function. Clearly, then, it is not enough to frame an explanation of a psychopathology purely in terms of mental or psychological constructs. But neither is it satisfactory to explain the condition only at the etiological or brain levels, in terms of gene mutations or receptor densities. We need to understand how genetic or brain differences lead to changes in behavior; in our model, these mechanisms can be elucidated at the neuropsychological level of analysis.

Complicating this model are bidirectional influences among the levels. The causal arrows do not run in only one direction, from the etiological or brain levels to behavior. A child's behavior constrains his or her experiences and creates certain environmental consequences, which in turn change brain development. Although experiences and environment do not change genes and DNA sequences, there is emerging evidence that they can influence gene activity. For example, early stress experiences can change the ex-

pression of the gene that produces the glucocorticoid receptor (Meaney et al., 1996). In rat pups, maternal separation causes increased corticotropin-releasing factor messenger RNA expression in several brain regions, including the amygdala (Caldji, Francis, Sharma, Plotsky, & Meaney, 2000). It should not be surprising that signals from the environment are capable of activating the DNA necessary to produce the appropriate proteins the organism needs to function in the environment, yet this direction of gene-environment interaction has rarely been appreciated (Gottlieb, 1998).

Four Levels of Analysis

With this introduction to the neuroscientific model of developmental psychopathology, we proceed to more detailed descriptions of the four levels of analysis. The symptoms of a disorder are end points of a complicated developmental process that includes multiple interacting levels and pathways. The science of developmental psychopathology has been successful at characterizing the outputs of this process, but is only beginning to understand its inputs. Therefore, we begin at the beginning, with the etiological level.

At the *etiological level*, both genetic and environmental factors work, separately or together, to cause psychopathology. As discussed earlier, there has been a tendency to view some conditions as more biological or genetic in origin and others as more social-environmental or interpersonal. It is becoming increasingly evident, however, that most developmental psychopathologies are caused by an interaction of genetic and environmental factors (Pennington, 2002) and that there is moderate genetic influence on most behavioral traits (Plomin & Rutter, 1998). Genes do not simply act very early in development and then hand the organism over to the environment. They turn off and on across the life span, and their expression can be changed by both the internal and external environments (Gottlieb, 1998). Psychopathologies likely result from specific combinations of biological and psychosocial risks (e.g., specific gene mutations, general susceptibility alleles, difficult life events, socioeconomic adversity, environmental exposures) and protective factors (good prenatal care, nutrition, protective alleles, parenting, safe physical environment, access to community resources and support). Studies at the etiological level use multiple research methods, including behavioral and molecular genetics.

Etiological factors do not “code” for behavior directly. They influence behavior through their impact on the process of brain development. Thus, the next level in our

model is the *brain mechanism level*. There are many examples of specific genetic mutations that affect the development of specific brain structures. Genetic variations can alter the migration of neurons, their organization into functional units such as columns and minicolumns, and their dendritic connections to other neurons. Neurons communicate with each other and with the rest of the body through chemical messengers (neurotransmitters and neuromodulators) that are released by one cell and bind to receptors on other cells. Receptors are proteins coded for by genes, and thus variations in their structure and function are under genetic control.

It is clear that genetics alone do not determine brain development. Since the landmark experiments of Hubel and Wiesel (1970) demonstrated the essential role that experiential input played in the organization and function of the feline visual system, it has been evident that the environment plays a very important role in shaping the developing brain. With approximately 10^{11} neurons and 10^{15} connections between them, it is logically impossible for 30,000 human genes to determine all the locations and connections of all the neurons in the brain (Changeux, 1985). Instead, the developing brain overproduces neurons, dendrites, and synapses, and experience “selects” which elements to preserve. During the course of typical development, those neurons and connections that are used are strengthened and those that are not used die. In some forms of psychopathology, such as Autism, there is evidence that these production and pruning processes do not take place in the typical way, resulting in disastrous deviations in development. The distribution of head size for children with Autism as a group is shifted by up to 1 standard deviation, and a substantial minority (up to 20%) exhibit macrocephaly (head circumference greater than the 97th percentile; Lainhart et al., 1997). A recent study reported that children with Autism are born with significantly smaller than normal head circumference, but by the first birthday have, as a group, mean head circumference at the 84th percentile, suggesting rapid and excessive early brain growth and failure of the typical pruning processes (Courchesne, Carper, & Akshoomoff, 2003).

As summarized earlier, it is clear that early experiences modify brain function and in this way may contribute to the development or prevention of psychopathology (see Grossman et al., 2003, for a recent review). Later experiences can also alter brain structure by adding or subtracting dendrites or synapses and by modifying existing synapses (Greenough, Black, & Wallace, 1987) and, possibly, by creating new neurons, even in adulthood (Gould,

Reeves, Graziano, & Gross, 1999), although this latter finding is controversial and more work is needed. Thus, experience and genetics play a major role in shaping the central nervous system across the life span.

Research methods used to explore brain level include animal lesion studies, neurochemical studies, and structural and functional neuroimaging. Relatively recent and rapid technological advances in neuroimaging have greatly illuminated brain processes involved in typical and atypical development.

The next level in our analytic framework is the *neuropsychological level*. This level bridges the gap between mind and body, making it the most challenging conceptually. One of its goals is to explain how variations in neural networks lead to changes in behavior. That is, *how* specifically do changes in the brain translate into functional differences, both psychopathological and normative, among people? An equally important goal of the neuropsychological level of analysis is to provide more parsimonious explanations of behavior than does a list or description of symptoms. A major presumption of the neuropsychological level is that variations in behavior can be reduced to variations in a smaller number of neuropsychological processes. The language of neuropsychological mechanisms is presumably closer to and more consistent with brain architecture than are symptoms or psychological constructs. With the rapid advances occurring in neuroscience, the neuropsychological level is poised to undergo rapid development. One of the most exciting recent developments at the neuropsychological level has been the use of functional neuroimaging technology to observe the brain as individuals engage in the execution of simple neuropsychological tasks. The rest of this chapter discusses this level of analysis more deeply.

Finally, the *symptom level* of analysis describes in a (supposedly) atheoretical manner the clusters of behaviors that define specific disorders. The developmental psychopathology field has been largely focused at this level thus far. The fruits of this labor include current diagnostic taxonomies, such as the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* and *International Classification of Diseases*. These systems have been refined through multiple revisions so that behavioral descriptions have become increasingly more reliable and valid. The symptom level of analysis continues to wrestle with a number of crucial issues, including (1) phenotypic variability, (2) external validity, (3) comorbidity, and (4) discontinuities across development. Many of these issues can be resolved using tools from neuropsychology, as discussed later.

Promises of the Neuropsychological Level of Analysis

Understanding the neuropsychological processes that underlie a disorder can help move the field of developmental psychopathology along in a number of ways.

Phenotypic Variability

One major concern of the symptom level of analysis is phenotypic heterogeneity. Different individuals diagnosed with the same condition do not present with the exact same symptom patterns. For most conditions, a list of potential symptoms is included in the diagnostic criteria, of which only a subset must be demonstrated for the diagnosis to be made. For some diagnoses, such as Autism, it is possible for two individuals to display completely different sets of symptoms (as only 6 symptoms from a list of 12 must be present). There are also symptoms that are common to a number of disorders, and there are a host of behaviors that are commonly associated with particular syndromes that are not included in the diagnostic criteria. One challenge for the symptom level of analysis is to explain this heterogeneity.

The neuropsychological level of analysis provides some assistance with this challenge. Symptoms can be classified into one of four categories: (1) primary or core symptoms, (2) correlated or concomitant symptoms, (3) secondary symptoms, and (4) artifactual symptoms (Pennington & Ozonoff, 1991; Rapin, 1987). Primary symptoms are close to universal in individuals with the disorder, are relatively specific to the disorder, have causal precedence in development, and persist with age. Most important, primary symptoms are the observable behaviors that are caused by the underlying neuropsychological deficit(s).

Correlated or concomitant symptoms have an etiology similar to that of core symptoms but arise from the involvement of different brain systems. For example, many children with dyslexia also demonstrate specific language impairments. These broader verbal disabilities are presumed to arise from the same genetic influences that cause dyslexia, but the brain systems disrupted are more extensive than those that lead to dyslexia. Not all children with a disorder will display correlated symptoms; symptom expression is dependent on the extent of disruption of brain development. Secondary symptoms are caused by primary or correlated symptoms. For example, the difficulties in peer relationships experienced by many children with ADHD are likely secondary to the primary symptoms of inattention, distractibility, and hyperactivity, which can make social interactions difficult. Finally, artifactual symptoms are those that appear to be associated with a dis-

order but are an artifact of biased ascertainment or other processes that serve to artificially increase the apparent co-occurrence of the behaviors. For example, behavioral disorders and delinquency in children with learning disabilities may be artifactual symptoms that are due to ascertainment biases.

Neuropsychological studies can be critical to determining which of many possible candidate symptoms are primary to a disorder. First, there must be a consistent pattern of results across studies demonstrating difficulties in the domain, relative to others without the disorder, matched on developmental level. Evidence of both specificity and universality can be provided by discriminant function analyses that attempt to classify individuals on the basis of their performance in the neuropsychological domain. Longitudinal and cross-sectional studies across a wide developmental range can address both persistence and precedence. Most powerful are prospective studies that identify and follow children at risk of developing a disorder, examining the onset, developmental trajectory, and predictive significance of key neuropsychological skills and deficits.

External Validity

A second way that neuropsychological analyses can be useful to developmental psychopathology is in establishing whether diagnostic classifications are meaningful and have explanatory power. Another issue raised at the symptom level of analysis is overlap among diagnostic categories. Some forms of developmental psychopathology share symptoms, raising concern that dimensional phenomena have been inappropriately parsed into categorical classifications. A powerful method of deciding whether two conditions are truly different is the process of external validation. The most essential component of this process is examining whether the conditions differ on external criteria not involved in the original definition of the syndromes (Fletcher, 1985). Typical means of establishing external validity involve comparison of the conditions' early history, developmental course, outcome, neuropsychological profiles, etiologies, and treatment response. Distinct syndromes should differ along at least one of these dimensions (Fletcher, 1985; Pennington, 1991). What is essential to external validation is that the dimensions on which the two conditions are compared fall outside the measurement domains used to initially define the syndromes.

One example of the potential power of the neuropsychological perspective in this regard comes from recent research on Autism Spectrum Disorders. Asperger's syndrome is a subtype of Autism Spectrum Disorders that

shares the social disabilities and restricted, repetitive behaviors of Autism, but in which language abilities are well developed and cognitive functioning is not impaired. Ever since it was first described in the English-language literature (Wing, 1981), there have been questions about its relationship to high-functioning Autism (i.e., Autism without accompanying mental retardation). Research comparing Asperger's syndrome and high-functioning Autism provides mixed evidence of their external validity, and a consensus is beginning to emerge that the two conditions are more similar than different. Neuropsychological studies have found impairments in executive function, social cognition, and motor skills in both subtypes (summarized in Ozonoff & Griffith, 2000). The one exception is that most research finds that individuals with Asperger's syndrome perform better on language tests than those with high-functioning Autism (Klin, Volkmar, Sparrow, Cicchetti, & Rourke, 1995; Ozonoff, South, & Miller, 2000), but this finding is likely an artifact of the group definition process requiring normal language onset for the Asperger's diagnosis. Some studies have found visual-spatial deficits in Asperger's syndrome (Klin et al., 1995) rather than the strengths typical of Autism, but several other studies have failed to replicate this finding and some have actually found visual-spatial superiorities in individuals with Asperger's syndrome (Manjiviona & Prior, 1995; Ozonoff et al., 2000; Szatmari, Tuff, Finlayson, & Bartolucci, 1990). Prior (2000, p. 8), in an editorial devoted to the issue of Asperger's syndrome's external validity, concluded, "One message to emerge from the papers is that it seems currently impossible to reliably distinguish between Asperger syndrome and high-functioning Autism on any acceptable clinical or pragmatic grounds." Supportive evidence has been provided from the etiological level, suggesting that high-functioning Autism and Asperger's syndrome often co-occur in families (Bolton et al., 1994; Jamain et al., 2003) and thus appear to share similar genetic influences (Volkmar, Klin, & Pauls, 1998). But the neuropsychological studies have been the most influential in this debate.

Comorbidity

Another significant issue that arises, but is not resolved, at the symptom level of analysis is that of comorbidity. It is not at all uncommon to find that a child suffers from more than one form of developmental psychopathology. Many explanations for this phenomenon have been proposed (Caron & Rutter, 1991; Simonoff, 2000), from artifactual reasons to causal relationships. Comorbidity is more likely

in a sample ascertained from a clinic, the most common source of research participants, as individuals with more symptoms are more likely to seek professional consultation. When affected individuals are recruited from the community, the apparent association between two disorders often disappears. Rater biases occur when a reporter (a parent, a teacher, or the child himself or herself) who is concerned about certain difficulties adopts a negative rating set (or “negative halo”), endorsing both symptoms that are truly present as well as additional behaviors that are not problematic. Another artifactual explanation for comorbidity is definitional overlap between diagnostic categories. For certain diagnoses, such as the externalizing behavior disorders, there is symptomatic overlap, such that the same or similar behaviors are included in multiple sets of diagnostic criteria. This can also increase the apparent rate of comorbidity.

Once these artifactual explanations have been ruled out, there are a number of explanations for the common occurrence of multiple developmental psychopathologies. Disorders may occur together because they share similar risk factors or because having one disorder places an individual at risk for the other disorder. That is, one disorder is a consequence of or secondary to the other. These hypotheses are not easily tested with neuropsychological models and are best examined through genetic analyses, including family, twin, and molecular studies. The interested reader is referred to Neale and Kendler (1995).

Developmental Discontinuities

A final set of questions that arise when examining developmental psychopathologies at the symptom level of analysis are related to discontinuities in symptom manifestation across development. It is more the rule than the exception to find that symptoms transform and change with age. A behavior that is prominent during one developmental period may be absent or of minor significance at another age. A symptom may manifest differently at different developmental periods, as in depression, in which the primary mood abnormality in adolescence and adulthood is low mood, but in earlier childhood is more often manifest as irritable mood. It is a fundamental part of our model that discontinuities at the level of observable behavior may hide continuities at deeper levels of analysis, those concerned with mechanisms (Pennington & Ozonoff, 1991). For example, hyperactive behavior is much less common in adults with ADHD than in children. If the underlying neuropsychological mechanism in ADHD is understood as a deficit in response inhibition (Barkley, 1997), then this apparent discontinuity is easily resolved. Hyperactivity is

conceptualized as only one of several manifestations of response disinhibition; others include difficulty curbing immediate reactions or thinking about consequences before doing or saying something, problems that are evident even in adults with ADHD. It must be noted that discontinuities in underlying neuropsychological deficits are also possible, but these are often more apparent than real, secondary to the necessity of using different measurement tools at different ages. If a broad sequence of developmentally appropriate measures of the neuropsychological domain are carefully chosen, then we often observe “heterotypic neuropsychological continuity” across development (Pennington & Ozonoff, 1991).

Further Promises

Neuropsychological perspectives may contribute to our understanding of developmental psychopathology in several additional ways. One possibility is that neuropsychological profiles can be used to clarify diagnosis or provide an objective diagnostic test. For some disorders, we have already begun to achieve this goal. We have a good understanding of the primary neuropsychological deficits associated with dyslexia, for example. These impairments fall in the domain of phonological processes, including phonological awareness and phonological decoding of written language (Torgesen, 1995). Specific performance profiles on neuropsychological tests (e.g., phonological processes significantly discrepant from age norms or from the child’s own intellectual level) are widely used for diagnostic purposes in clinics that serve children with learning disabilities and in schools. The neuropsychology of dyslexia is a mature field, relative to other forms of developmental psychopathology, and for most disorders, including those we discuss later in this chapter, the promise of using neuropsychological functioning to clarify diagnosis is far from being achieved. In Autism, for example, there has been great debate about the nature of the underlying neuropsychological dysfunction. In the first edition of these volumes, Pennington and Welsh (1995) characterized Autism as a primary disorder of social cognition, whereas newer conceptualizations emphasize core deficits in emotional processes, and theories that focus on other cognitive abnormalities also exist. Using performance profiles on neuropsychological tests to bootstrap diagnosis of Autism Spectrum Disorders, while conceptualizations of the neuropsychological phenotype are still in flux, would be a mistake.

Another potential promise of the neuropsychological level is to better match treatments to subtypes within a disorder. This goal has again been achieved in the dyslexia field, where the treatments are explicitly geared toward im-

provement of the deficient phonological skills (e.g., Lindamood & Lindamood, 1998; Torgesen & Bryant, 1994). As another example, better understanding of the neuropsychology of ADHD might improve our efforts to target particular symptoms more precisely with medications and behavioral interventions that affect selective processes, such as working memory, response inhibition, and delay aversion (Castellanos & Tannock, 2002).

So far, these examples illustrate how research at the neuropsychological level might refine understanding at the behavioral or symptom level. Neuropsychological influences on other levels are also possible (e.g., neuropsychological research informing understanding of etiologic mechanisms). In fact, this is what we argue is the case in the PTSD field. Many, probably most, developmental psychopathologies are influenced by genetic factors, yet none follows classic Mendelian patterns of inheritance. In even those disorders with high heritability, such as Autism, what is inherited does not appear to be the disease itself, but a broader set of behaviors and traits that are more or less normally distributed throughout the population (Bailey, Palferman, Heavey, & LeCouteur, 1998). For this reason, using diagnostic classifications to find susceptibility genes would not be predicted to be successful, and indeed this has been the case for Autism (Piven, 2001). Neuropsychological abilities and deficits are often dimensionally distributed, both within the general population and within affected families, and thus may better index genetic liability than dichotomous diagnostic categories.

It has also been proposed that specific neuropsychological patterns may have distinct etiologic bases. One example comes from Williams' syndrome, a rare genetic disorder caused by a small deletion on chromosome 7. Individuals with Williams' syndrome have mental retardation, but their cognitive abilities are not affected similarly across the board. Visuospatial abilities, such as pattern construction, are significantly impaired, but verbal abilities are relatively spared (Bellugi, Mills, Jernigan, Hickok, & Galaburda, 1999). The microdeletion on chromosome 7 typically includes the genes for both elastin, a protein in connective tissue, and LIM-kinase, a protein co-enzyme expressed in the brain. However, the deletion can vary in size, and it has been proposed that genotype-phenotype mapping may elucidate the genes responsible for specific physical, behavioral, and neuropsychological manifestations of the syndrome. Two samples of individuals with Williams' syndrome have been described, one of which had the elastin but not the LIM-kinase gene deleted and the other of which had both genes deleted. In the first sample, the typical visuoconstructive deficit was not evident, lead-

ing to the suggestion that this cognitive ability is influenced by the LIM-kinase gene (Frangiskakis et al., 1996). A later study failed to replicate this finding, however (Tassabehji et al., 1999). It has also been suggested that distinct components of the dyslexia phenotype are associated with distinct genotypes (Grigorenko et al., 1997), but this study, too, awaits replication. Nevertheless, these syndromes provide exciting examples of the potential of the neuropsychological method to guide us toward etiological mechanisms (see also Flint, 1999; Fossella et al., 2002).

Neuropsychological Domains Relevant to Developmental Psychopathology

The neuropsychological level of analysis seeks to provide a bridge between behavior and the brain. The brain is a highly complex organ, containing billions of neurons and trillions of connections among them. Similarly, human behavior is highly complex. The task of mapping brain and behavior would be daunting, if not impossible, if there were not some model for describing the functional units of the human nervous system. Two such approaches are the traditional lesion model of neuropsychology and the functional model described by Luria (1966).

Luria's Model

Luria (1966) described three functional brain units: the arousal/motivation system, the perception/memory system, and the action selection system, each of which map onto integrated but distinct neural circuits. The perception/memory system creates and stores and/or activates existing representations of the organism's context that come from the environment through the sensory organs to the brain. The neural circuits involved in this process lie primarily in the posterior cortex and the hippocampus, but there are rich reciprocal connections to other areas of the brain that permit these representations of environmental context to affect behavior and vice versa. Disruptions of components of the perception/memory system occur in a variety of neurological diseases, such as Alzheimer's and other dementias, and focal lesions due to stroke or injury, but few forms of developmental psychopathology appear due to involvement of this system.

Representations generated by the perception/memory system serve as inputs to the motivation/arousal system. This component of Luria's organizational model accomplishes one of the key adaptive tasks for any behaving organism, which is to adjust motivational state to fit changing environmental circumstances. This system appraises the

context in which the organism finds itself and generates appropriate arousal and motivational states. When the system is dysfunctional, as in the development of psychopathology, motivational states inappropriate to context may be activated. The neural components of the motivation/arousal system include the neocortex, the limbic system, and the brain stem. At the lowest level, brain stem nuclei with diffuse projections to other regions release excitatory and inhibitory neurotransmitters that modulate arousal in the rest of the brain to match current contexts and goals. Circuits in the brain stem and midbrain also mediate automatic behavioral responses to certain environmental stimuli (e.g., pain, taste). Some of these responses are reflexive, but other motivational responses can be modified at higher levels. The amygdala, for example, allows the rapid extraction of valence from environmental input and the learning of associations between stimuli. The orbitofrontal cortex is specialized for rapidly reversing the link between reinforcers and actions as the context changes, inhibiting or reversing motivated behaviors mediated by lower structures. Thus, there are some virtually innate motivational states that appear to have almost reflexive effects on behavior, but higher structures can modify these responses. The learning of new associations mediated by the amygdala is rapid, which is important for survival, but not flexible (e.g., learned associations are not quick to be unlearned), which can be disadvantageous and lead to psychopathology, such as mood and anxiety disorders.

The action selection system, modified by input from the motivation system, then plans and executes actions (and thoughts) to deal with the environmental context and, in humans, to contend with future contexts. When current and future conditions differ, this ability to select responses evoked by simulated contexts can give rise to both adaptive behaviors, such as foresight and courage, and maladaptive behaviors seen in certain psychopathologies, such as avoidance. Because the range of possible actions is infinite, it is hypothesized that the motivation system helps the organism quickly narrow the range. One important functional component of the action selection system serves to further constrain possible behavior choices by *deselecting* options that are not appropriate through inhibitory processes. Many developmental psychopathologies appear to involve difficulty both in selecting context-appropriate actions and in inhibiting context-inappropriate actions; these deficits may be manifest as hyperactivity, echolalia, tics, compulsions, stereotypies, ruminations, antisocial behavior, hallucinations, and/or delusions.

Three main brain structures interact in the action selection system: the frontal cortex, the basal ganglia, and the

thalamus. The prefrontal cortex makes connections with components of the basal ganglia, which in turn makes connections to the thalamus, which sends a feedback connection to prefrontal cortex (Casey, Durston, & Fossella, 2001). Each level of the circuit performs a somewhat different function. The prefrontal cortex mediates planning. It receives and integrates input from all over the brain, providing contextual constraints on the action selection system and exerting top-down control over areas of the cortex. Different portions of the prefrontal cortex maintain different kinds of information about current context in working memory to guide action. The basal ganglia then play an important role in initiating actions (O'Reilly & Munakata, 2000); when sufficient evidence accumulates that a given action is warranted, circuits within the basal ganglia fire, leading to reduced thalamic inhibition of the given areas of the prefrontal cortex, resulting in output (action or thought).

Lesion Models

Another taxonomic approach comes from the lesion model of adult neuropsychology, in which acquired damage to specific brain structures defines particular cognitive deficits. The functional domains defined by the lesion model have traditionally included executive function, spatial reasoning, phonological processing, social cognition, and memory. In the traditional neuropsychological model, these functional systems are subserved by different cortical networks. Certainly other functional systems (e.g., motor) exist, but these appear less relevant to developmental psychopathology. Here we consider the domains most often impaired in developmental psychopathologies.

Executive functions are goal-directed, future-oriented behaviors that include such components as organization, planning, goal generation and monitoring, inhibition, and flexibility. Deficits in these behaviors are commonly found as a result of injury to the prefrontal cortex. Goldman-Rakic (1987) emphasized the role of the prefrontal cortices in holding goal-related representations online (in so-called working memory), allowing the organism to solve problems that cannot be worked out strictly on the basis of previously learned associations. Cohen and Servan-Schreiber (1992) postulated that the core function of the prefrontal cortices is to maintain an internal representation of context in working memory to guide behavior in complex or novel situations. Thus, when an organism must compute a new response, the frontal cortex is used to hold online relevant representations of context and goals, as well as partial and final products of computation, in a dynamic system. Proper functioning of this system is required for (1) strategic allo-

cation of attention, (2) inhibition of irrelevant responses, (3) appropriate shifting of cognitive set, (4) relating information appropriately over time and space, and (5) adjusting behavior in relation to evolving contexts. Much of social behavior and social development would appear to depend on these capacities. Consequently, we would expect the domain of executive functions to be particularly important for understanding deficits in social behavior, which is the domain of much of developmental psychopathology. Indeed, executive function deficits are being found in a number of developmental psychopathologies.

Social cognition is the domain of neuropsychology that includes the information-processing mechanisms that underlie social behavior. Specific functions that fall in this domain are emotion perception, face processing, social perspective taking, pragmatic aspects of language production and comprehension, attachment, affect regulation, self-knowledge, and emotional biases on judgment (Ochsner & Lieberman, 2001). As just discussed, some aspects of social cognition appear to require executive functions and to be mediated by the prefrontal cortex, so this is not a wholly independent category. Other parts of the brain are also important for some social and emotional functions, and hence separate pathologies that involve disruptions in these neural systems are possible. For example, face perception depends on regions of the visual cortex, such as the fusiform gyrus (also sometimes known as the “fusiform face area” or FFA), as well as aspects of the temporal lobes, such as the superior temporal sulcus (STS; Haxby, Hoffman, & Gobbini, 2000; Kanwisher, McDermott, & Chun, 1997). The amygdala is thought to play a major role in identifying negative affect, particularly fear, and recognizing threat (Adolphs et al., 1999). Functional imaging studies suggest that similar areas (orbitofrontal cortex, FFA, STS) are activated when mental states are processed (Gallagher et al., 2000; Stuss, Gallup, & Alexander, 2001).

A third functional system is the *phonological processing* system, which in the majority of individuals is subserved by the perisylvian areas of the left hemisphere, including Wernicke’s area in the posterior left temporal lobe and Broca’s area in the premotor portion of the left frontal lobe. Phonological abilities have a protracted course of development; consistent with this and with their relatively late appearance on an evolutionary scale, phonological processes are subject to considerable individual variation, and disorders of phonological processing have a high prevalence rate (up to 10% of the population). Language processes are very important in understanding developmental psychopathology, both because primary deficits in language processes can disrupt the development of social

skills and because primary deficits in social skills can disrupt language development. Given this close reciprocal relationship, it is not surprising that many developmental psychopathologies involve associated symptoms consistent with deficient phonological processes, such as comorbid language disorders and language-based learning disabilities. Understanding the causal basis of such overlap is one of the challenges for developmental psychopathology.

The lesion model’s functional organization of neuropsychological systems has a long research tradition and has often been used in research studies. Its assumption of one-to-one structure-function relationships appears to be too simplistic, however. Brain functions are rarely localizable to specific cortical regions but are products of the aggregate functioning of cortical and subcortical networks. One of the most serious weaknesses of the lesion model is that it is not a developmental model. Developing brains exhibit greater plasticity than mature ones. Consequently, when they are injured, there is not the same loss of function as in adults, with alternative neural connections potentially able to support behavior (Moses & Stiles, 2002). Luria’s functional organization of the central nervous system is appealing because it appears more consistent with accumulating neuroscientific evidence of how the brain works. Both models are simplifications of highly interactive, complex systems, however, and both have limitations, which we turn to later in the chapter. Nonetheless, both afford some heuristic for translating from behavior to brain and back again and current neuropsychological research on developmental psychopathology, such as that reviewed in the next section, has relied on these models, so we use them for the time being.

THE NEUROPSYCHOLOGY OF SPECIFIC DEVELOPMENTAL PSYCHOPATHOLOGIES

In this section, we examine two developmental psychopathologies in depth: Autism and Posttraumatic Stress Disorder. The Autism Spectrum Disorders provide fertile ground for examining the utility of the four-level model of developmental psychopathology just outlined. A large amount of research has been conducted at each of the levels, but the etiologies and brain mechanisms involved and the mechanisms by which they lead to symptoms are still largely unknown. This creates many explanatory voids that the neuropsychological level can attempt to fill. Indeed, the lack of definitive etiologies has stimulated a great deal of neuropsychological research since the disorder was first described by Kanner (1943). Published work has moved

from largely descriptive accounts of symptoms to sophisticated empirical delineations of information-processing profiles. Several unifying neuropsychological models that attempt to bring together all the symptoms of Autism under one roof have been proposed, stimulating more experimental research and new scientific debates. In this sense, the neuropsychology of Autism is a much broader and more active field than that of PTSD, the other psychopathological condition we discuss in this chapter, which is more focused, perhaps because its etiology appears simpler. As the Autism field has gained maturity, however, new questions have been raised and a variety of potential limitations of the neuropsychological model of developmental psychopathology have become apparent. The comparison of Autism, a disorder with high heritability, and PTSD, a condition with (by definition) major environmental contributions to etiology, provides other interesting contrasts, including the relative mind-body problems each face, how their respective explanatory models have attempted to resolve these issues, and how research at different levels of analysis has proceeded at different rates and with varying degrees of dependence/independence.

For each disorder, we begin with the fourth level of analysis, that is, definition and description of the symptoms. We then proceed from level 1, the etiological level, through level 3, the neuropsychological level. It should be noted that this ordering of the levels is practical, but not conceptually elegant. By placing symptoms and background first, this order makes it easier for the reader to follow the other levels of analysis. By placing neuropsychology last, however, this order de-emphasizes the fact that this level forms a bridge between brain and behavior. For both Autism and PTSD, we report the literature in such a way as to highlight both the promises of the neuropsychological approach outlined earlier and the apparent limitations of the approach that are emerging. This latter topic is further developed in the final section of the chapter.

AUTISM SPECTRUM DISORDERS

In this section, we review the empirical research on the group of conditions collectively called Autism Spectrum or Pervasive Developmental Disorders.

Level 4: Symptoms, Diagnostic Definitions, and Epidemiology

As specified in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (*DSM-IV-TR*; American Psychiatric Association [APA], 2000), there

are five Pervasive Developmental Disorders (PDD): Autistic Disorder, Asperger's Disorder, Rett's Disorder, Childhood Disintegrative Disorder, and Pervasive Developmental Disorder Not Otherwise Specified. Symptoms of Autistic Disorder fall in the three areas of social relatedness, communication, and behaviors and interests. In the social domain, symptoms include impaired use of nonverbal behaviors (e.g., eye contact, facial expression, gestures) to regulate social interaction, failure to develop age-appropriate peer relationships, little seeking to share enjoyment or interests with other people, and limited social-emotional reciprocity. Communication deficits include delay in or absence of spoken language, difficulty initiating or sustaining conversation, idiosyncratic or repetitive language, and imitation and pretend play deficits. In the behaviors and interests domain, there are often encompassing, unusual interests, inflexible adherence to nonfunctional routines, stereotyped body movements, and preoccupation with parts or sensory qualities of objects (APA, 2000). To meet criteria for Autistic Disorder, an individual must demonstrate at least 6 of the 12 symptoms, with at least two coming from the social domain and one each from the communication and restricted behaviors/interests categories. At least one symptom must have been present before 36 months of age.

The onset of Autism occurs before age 3, at two peak periods. The majority of children display developmental abnormalities within the first 2 years of life. A smaller group of children with Autism display a period of normal or mostly normal development, followed by a loss of communication and social skills and onset of Autism (Kurita, 1985). The regression occurs most commonly between 12 and 24 months of age, although in rare cases can occur after age 2 but before the third birthday.

Asperger's Disorder (or Asperger's syndrome) shares the social disabilities and restricted, repetitive behaviors of Autism, but language abilities are well developed and intellectual functioning is not impaired. Its symptoms are identical to those just listed for Autistic Disorder, except that there is no requirement that the child demonstrate any difficulties in the second category, communication. Although described almost 60 years ago by Austrian pediatrician Hans Asperger (1944), the Asperger's syndrome diagnosis was not included in the *DSM* until the fourth edition. In the *DSM-IV* diagnostic system, the main point of differentiation from Autistic Disorder, especially the higher-functioning subtype, is that those with Asperger's syndrome do not exhibit significant delays in the onset or early course of language. As specified in the *DSM-IV*, nonechoed, communicative use of single words must be

demonstrated by age 2 and meaningful phrase speech by age 3. Most parents of children with Asperger's syndrome are not concerned about early language development and may even report precocious language abilities, such as a large vocabulary and adult-like phrasing from an early age. Autistic Disorder must be ruled out before a diagnosis of Asperger's syndrome is justified. *DSM-IV-TR* mandates that the diagnosis of Autism always takes precedence over that of Asperger's syndrome. Thus, if a child meets criteria for Autistic Disorder, the diagnosis must be Autism even if he or she displays excellent structural language, average or better cognitive skills, and other typical features of Asperger's syndrome.

Individuals who meet criteria for Autistic Disorder and are intellectually normal are considered high functioning. Research comparing Asperger's syndrome and high-functioning Autism provides mixed evidence of their external validity. Early history differences are evident between the disorders, with children with Asperger's syndrome showing fewer and less severe symptoms and better language in the preschool years than children with high-functioning Autism, but these group differences are likely artifacts of the diagnostic definitions (Ozonoff et al., 2000). Follow-up studies demonstrate similar trajectories in outcome (Ozonoff et al., 2000; Szatmari et al., 2000). As summarized earlier, neuropsychological research suggests that the two conditions are more similar than different.

Two other conditions also appear in *DSM-IV* in the PDD category: Rett's Disorder and Childhood Disintegrative Disorder. Both involve a period of typical development, followed by a loss of skills and regression in development. The classic symptoms of Rett's Disorder, seen primarily in females, include unsteady gait, lack of language, lack of functional hand use, almost constant stereotyped hand movements, including repetitive wringing, "washing," twisting, clapping, or rubbing of the hands in the midline, very severe cognitive deficits, and lack of typical social interaction. Recently, a gene was isolated on the X chromosome MECP2, which appears responsible for most cases of Rett's Disorder (Amir et al., 1999). In Childhood Disintegrative Disorder, an abrupt and severe regression occurs after at least 2 (and up to 10) years of normal development. After the loss of skills, the child has all the characteristics of severe Autism and severe mental retardation, but unlike typical Autism, there is little developmental growth after treatment and the condition continues as a chronic, severe, developmental disability.

The fifth and final condition that falls within the PDD category is Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS). This label is used for children

who experience difficulties in at least two of the three Autism-related symptom clusters (clear difficulty relating to others, as well as either communication problems or repetitive behaviors) but who do not meet criteria for any of the other PDDs. The same list of 12 symptoms is used to diagnose PDD-NOS, but only one difficulty in the "reciprocal social interaction" domain and one symptom from either the "communication deficits" or "repetitive, restricted behaviors" domains is required. Children with PDD-NOS have autistic-like behaviors and difficulties, but either have too few symptoms or a different pattern of symptoms than the other conditions in the PDD category. For example, a child might be diagnosed with PDD-NOS if he or she displayed only four of the *DSM-IV* symptoms (ruling out Autistic Disorder), displayed a delay in language onset (ruling out Asperger's syndrome), and showed no regression in development (ruling out both Rett's and Childhood Disintegrative Disorders).

Epidemiology

Early research suggested that Autism (strictly defined, meeting full criteria for the disorder) occurred at the rate of 4 to 6 affected individuals per 10,000 (Lotter, 1966; Wing & Gould, 1979). An influential study conducted in the mid-1980s broadened diagnostic criteria somewhat and found a rate of 10 per 10,000 in a total population screening of a circumscribed geographic region in Canada (Bryson, Clark, & Smith, 1988). Newer studies have utilized standardized diagnostic measures of established reliability and validity and employed active ascertainment techniques. These surveys have given prevalence estimates of 60 to 70 per 10,000 or approximately 1/150 across the spectrum of Autism and 1/500 for children with the full syndrome of Autistic Disorder (Chakrabarti & Fombonne, 2001). One obvious reason for the rise in rates is that more recent research has examined all Autism Spectrum Disorders, whereas early surveys looked at rates of only strictly defined Autism. However, in studies that have broken down the rates by specific *DSM-IV* PDD subtypes, it is clear that the prevalence of classic Autism itself is higher. This may suggest that broader criteria or better detection of mild cases alone are not enough to account for the rise in prevalence. Chakrabarti and Fombonne (2001) reported a rate of 16.8 per 10,000 for *DSM-IV* Autistic Disorder, which is 3 to 4 times higher than suggested in the 1960s and 1970s and over 1.5 times higher than thought in the 1980s and 1990s.

Several reasons for the rising prevalence rates have been proposed, from artifactual explanations to newly emerging environmental and biological risk factors. In the first category are increased awareness among clinicians and the

general public, better identification and referral practices, more sensitive diagnostic tools, and broader classification systems. There is no doubt that the ability of clinicians to identify more subtle manifestations of Autism Spectrum Disorders and to discriminate Autism from mental retardation has improved; it is also clear that the current diagnostic system of *DSM-IV* is broader in the net it casts than were previous classification systems. Whether these changes in referral and practice alone can account for the large increase is uncertain, and hypotheses abound about environmental factors that may have emerged in the past few decades to put infants and young children at greater risk for developing Autism. These are covered, along with other etiologic factors, in the next section.

Level 1: Etiology—Genes, Environmental Factors, and Interactions

Kanner (1943, p. 42) suggested that autistic children were born with “an innate inability to form the usual, biologically provided affective contacts with people.” Later, however, his thinking came into line with that of his contemporaries trained in the psychoanalytic tradition predominant at the time. It was mistakenly suggested that Autism was the result of inadequate nurturance by emotionally cold, rejecting parents (Bettelheim, 1967), a theory that prevailed until the late 1960s. Rimland (1964) did a tremendous service to the field when he provided powerful arguments that Autism had an organic etiology. The finding that approximately 25% of children with Autism developed seizures in adolescence also strongly suggested that Autism was a neurodevelopmental condition with underlying organic brain dysfunction (Schain & Yannet, 1960).

Genetic factors appear to play a strong role in the development of Autism (Bailey et al., 1995; International Molecular Genetic Study of Autism Consortium, 2001). The recurrence risk for Autism after the birth of one child with the disorder is 3% to 6%, a rate that far exceeds that in the general population (Bailey, Palferman, et al., 1998). The concordance rate for Autism in monozygotic (MZ) twins is greatly elevated relative to that for dizygotic (DZ) twins. The most recent twin studies, which used standardized diagnostic measures and total population screening, found concordance rates for strictly defined Autistic Disorder of 60% in MZ pairs, but only 5% in DZ pairs. MZ concordance rates of up to 90% are reported when including social and communication abnormalities broader than Autistic Disorder. Twin studies yield a heritability estimate greater than .90 (Bailey et al., 1995; LeCouteur et al.,

1996). And there is evidence of familial transmission of an extended set of cognitive and social anomalies that are milder than but qualitatively similar to Autism (the so-called broader Autism phenotype; Bailey, Palferman, et al., 1998). Family members also suffer from higher than average rates of anxiety and affective disorders and learning disabilities. Collectively, these features of the broader Autism phenotype have been found in 15% to 45% of family members of people with Autism in different samples (Bailey, Palferman, et al., 1998).

Advances in the molecular genetics of Autism have been rapid, but the results are so far inconclusive. One reason is that the inheritance pattern appears far from simple, with statistical models suggesting that several and perhaps as many as 10 genes are involved in conferring susceptibility (Pickles et al., 1995; Risch et al., 1999). Case reports have demonstrated a link between Autism and a wide variety of chromosomal anomalies, with one review (Gillberg, 1998) reporting associations with all but three chromosomes. It is not yet clear which associations are random and which may provide clues about etiology. The one cytogenetic abnormality that has been consistently replicated in a small proportion of children with Autism is a duplication of material on chromosome 15 (Rutter, 2000). Molecular genetic studies have found linkage and/or association with a number of different chromosomal regions, with the strongest support and replication across studies for sites on 2q, 7q, and perhaps 13q (Collaborative Linkage Study of Autism, 2001; International Molecular Genetics Study of Autism Consortium, 2001).

Twin studies also make it clear that Autism is not a purely genetic disorder, as concordance rates among identical twins fall short of 100%. There can be tremendous phenotypic variability even among MZ twins, with one twin displaying severe Autism and the other the broader phenotype, for example. Fifty point IQ differences within MZ pairs have been reported (Rutter, 1999). The search for other factors that influence the development and severity of Autism is intense and has received much media attention. It has been suggested that environmental factors, including vaccination, heavy metal or pesticide exposure, viral agents, and food products, may interact with genetic susceptibility to trigger Autism, cause it alone, or mediate the expression and severity of the disorder (Hornig & Lipkin, 2001). A few of the most influential theories regarding environmental factors are reviewed in this section.

Many parents report gastrointestinal (GI) disturbances in their children with Autism, such as persistent diarrhea, constipation, abdominal distention, or pain. There are mul-

multiple theories for the origin of GI pathology in Autism, including food allergies, metabolic problems, and disruption of gut flora due to antibiotic overuse. The potential environmental etiologic agent that has received the most attention is immunizations. Wakefield et al. (1998) described a case series of 12 children with GI disturbances that were reported to begin around the time that autistic behaviors became evident. He postulated that these children had a new subtype of “regressive Autism” that was induced by the measles, mumps, rubella (MMR) vaccination. The postulated mechanism was a persistent measles virus infection resulting in damage to the intestinal lining, increased permeability, and absorption of toxic peptides that cause central nervous system dysfunction and behavioral regression. Three recent studies do not support this hypothesis, however. Taylor et al. (1999, 2002) identified 498 children with Autism born since 1979 and linked clinical records to independently recorded immunization data. No evidence of a change in trend in incidence or age at diagnosis was associated with the introduction of the MMR vaccination in 1988. The most recent study followed all children born in Denmark between 1991 and 1998 and strongly supported the findings of Taylor and colleagues, again failing to find any increase in vaccinated relative to unvaccinated children and any temporal clustering of cases of Autism after immunization (Madsen et al., 2002).

Another proposed environmental risk factor for Autism is exposure to environmental toxins during the prenatal or infancy periods (Bernard, Enayati, Roger, Binstock, & Redwood, 2002; Edelson & Cantor, 1998; London & Etzel, 2000) or metabolic abnormalities that impair the natural detoxification process. It is well established that certain early exogenous exposures (e.g., mercury, lead, ethanol) can have neurotoxin effects and lead to developmental disabilities (Burbacher, Rodier, & Weiss, 1990; Needleman, Schell, Bellinger, Leviton, & Allred, 1990), although none has been specifically associated with Autism in the empirical literature. One possible source of excessive mercury exposure that has received attention is thimerosal, an ethylmercury-based preservative included in several vaccines to prevent bacterial contamination. MMR, polio, and varicella vaccines have never contained thimerosal, but it has been included in multiple-use vaccines since the 1930s. Concerns have been raised recently that the cumulative exposure to ethylmercury, via thimerosal, is now far greater than in the past due to the increased number of vaccines given to children, especially before age 2. This is a controversial theory that has provoked strong reactions on both sides, but current scientific evidence has not yet proven or

disproven a link between thimerosal and neurodevelopmental disorders (Stratton, Gable, & McCormick, 2001).

To summarize this section, research at the etiologic level is accumulating rapidly, and there are many theories about causal agents. All theories postulate biological mechanisms that are thought to produce brain changes that lead in turn to the symptoms of Autism. There are no viable social-environmental hypotheses of Autism etiology, but a diathesis-stress model (with the environmental stressors biological in nature) may have utility. We turn next to the brain changes that the putative etiologic agents are thought to cause.

Level 2: Brain Mechanisms

Kanner's (1943) original description noted unusually large head size in a proportion of children with Autism, and macrocephaly (head circumference >97th percentile) has been confirmed in approximately 20% of individuals with Autism (Fombonne, Roge, Claverie, Courty, & Fremolle, 1999; Lainhart et al., 1997). The increase in head volume reflects an increase in brain volume, which is not apparent at birth but is present by the first birthday (Courchesne et al., 2003) and is hypothesized to be due to both overgrowth and the failure of normal pruning mechanisms (Piven, Arndt, Bailey, & Andreasen, 1996). Recent studies have suggested that excessive growth may be followed by a period of abnormally slow or arrested growth later in childhood (Courchesne, 2004).

Aside from macrocephaly, structural neuroimaging studies have yielded inconsistent results, possibly stemming from methodological issues such as small samples, inappropriate or no control groups, and inconsistent use of covariates, including age, gender, IQ, and total brain volume. Studies have demonstrated decreased volume of the cerebellar vermis, particularly lobules VI and VII (Courchesne, Yeung-Courchesne, Press, Hesselink, & Jernigan, 1988), but this finding has not always been replicated by other research teams (Hardan, Minshew, Harenski, & Keshavan, 2001; Piven, Bailey, Ranson, & Arndt, 1997). The body and posterior portions of the corpus callosum have been reported to be significantly smaller than normal (Piven et al., 1997). Saitoh, Karns, and Courchesne (2001) found that the area dentata (dentate gyrus and CA4) of the hippocampus was significantly smaller on the MRI of children with Autism than normal children, and Sparks et al. (2002) reported increased hippocampal and amygdala volumes in children with Autism Spectrum Disorders.

Structural MRI results are variable across studies and do not point to any signature abnormality characteristic of

Autism Spectrum Disorders, and regional volumetric changes do not directly measure brain function and thus are not the most sensitive index of the brain-level mechanisms operative in these disorders. Functional brain imaging studies have more consistently demonstrated differences in samples of children with Autism (Cody, Pelphrey, & Piven, 2002). Two recent studies found reduced cerebral blood flow bilaterally in the superior temporal gyrus and left frontal cortex (Ohnishi et al., 2000; Zilbovicius et al., 2000) in children with Autism at rest (e.g., not engaged in task performance). In activation studies that examine brain regions used to perform specific tasks, several research groups have found that individuals with Autism show reduced or different patterns of brain activity compared to controls. In one study in which participants had to identify facial expressions of emotion, those with Autism activated the fusiform gyrus (part of the temporal lobes), the left amygdala, and the left cerebellum significantly less than controls did (Critchley et al., 2000). Two other studies, discussed in more detail in the neuropsychology section, found reduced or absent activation of similar brain regions during social reasoning tasks (Baron-Cohen et al., 1999; Schultz et al., 2000). Different patterns of activation were also found in a study that examined brain function during a visual search task that is often a strength for individuals with Autism. Participants with Autism demonstrated reduced activation of prefrontal cortex but increased activation of ventral occipitotemporal networks relative to controls (Ring et al., 1999). Thus, even when performance is not deficient, the brains of people with Autism Spectrum Disorders show distinct functional differences from typical patterns.

The changes present in detailed autopsy studies of a limited number of individuals with Autism (most of whom also had significant mental retardation and seizures) consist of increased neuronal density, particularly in the hippocampus, olivary dysplasia, scattered areas of cortical and white matter dysplasia, including neuronal ectopias, and other nonspecific developmental abnormalities in the brain stem and cerebellum (Bailey, Luthert, et al., 1998; Palmen, van Engeland, Hof, & Schmitz, 2004). Bauman and Kemper (1988) reported increased cell packing, reduced cell size, and reduced dendritic connections in the limbic system. Casanova and colleagues (Casanova, Buxhoeveden, Switala, & Roy, 2002) have developed a computer program that can quantify the size and density of the parallel vertical columns that organize the human neocortex. The basic unit is the minicolumn, a chain of neurons oriented perpendicular to the cortical surface, surrounded by axons and

dendrites that make lateral connections. Casanova et al. found smaller, less compact, and more numerous minicolumns in the superior and middle temporal gyrus and superior and middle frontal gyrus in those with Autism, relative to typical and dyslexic controls. As we discuss in the next section, these findings have potential implications for neuropsychological theories of Autism.

Level 3: Neuropsychology

Research at the neuropsychological level of analysis has been very active, perhaps because the behavior of individuals with Autism has always made clear that the profile of strengths and weaknesses is an interesting and unusual one. In Kanner's (1943) original paper, he highlighted both deficits and talents. He mentioned precocious reading, prodigious memory, and well-developed visual-spatial skills, alongside a fundamental inability to relate to others, a failure to use language to convey meaning, and an obsessive desire for the maintenance of sameness. Several subsequent studies have demonstrated an uneven profile of ability in Autism, with impaired performance on tasks that require language, abstract reasoning, integration, and sequencing, but spared ability on tasks that require visual-spatial processing, attention to detail, and rote memory abilities (Green, Fein, Joy, & Waterhouse, 1995). Next, we describe empirical findings in the domains defined by traditional neuropsychological conceptualizations of the brain's functions (e.g., attention, memory, social cognition, language, and executive functions), highlighting both empirical findings and theoretical models.

Attention

Many investigations have documented attentional abnormalities in individuals with Autism (for a review, see Allen & Courchesne, 2001), but the deficits are variable across different components of attention and present a different profile from other disorders. It has been noted in case studies and in the clinical literature for many years that individuals with Autism appear to have "overfocused" attention, responding to only a subset of environmental cues during learning situations (e.g., Lovaas, Koegel, & Schreibman, 1979). Deficits relative to controls have been found in the shifting of attention between sensory modalities. In one study, adults with average IQ and Autism performed as well as typical controls on a task that required no shifting of attention, but performance was over 6 standard deviations below that of controls when rapid alternation of attention between auditory and visual channels was required

(Courchesne et al., 1994). Several studies using the visuospatial orienting task of Posner (1980) have documented that people with Autism take longer to disengage and move attention than controls matched on ability (Casey, Gordon, Mannheim, & Rumsey, 1993; Townsend et al., 1999; Wainwright-Sharp & Bryson, 1993). In contrast, a number of studies have suggested that the ability to *sustain* attention is a relatively spared ability in Autism, with normal function on continuous performance tests found in several investigations (Buchsbaum et al., 1992; Casey et al., 1993; Garretson, Fein, & Waterhouse, 1990; Goldstein, Johnson, & Minshew, 2001; Noterdaeme, Amorosa, Mildenerger, Sitter, & Minow, 2001). This profile of attentional strengths and weaknesses distinguishes children with Autism from those with ADHD. Children with ADHD have little difficulty disengaging and shifting attention (Swanson et al., 1991), but they demonstrate severe impairment in sustaining attention and controlling impulses.

Memory

The memory of people with Autism has been extensively studied, stimulated by early research that likened Autism to amnesia (Boucher & Warrington, 1976). The amnesic analogy has received some support from the neuroanatomical research reviewed in the previous section (Aylward et al., 1999; Bauman & Kemper, 1988; Saitoh et al., 2001; Salmond, de Haan, Friston, Gadian, & Vargha-Khadan, 2003) and renewed interest due to the current popularity of an “amygdala theory” of Autism (Baron-Cohen et al., 2000). Proposed similarity at the neuropsychological level has been more controversial. Amnesic subjects typically demonstrate three patterns: (1) intact immediate and short-term memory but deficient long-term memory, (2) reduced primacy but normal recency effects, and (3) a flatter learning curve. Similar patterns have been hypothesized to also exist in Autism (Bachevalier, 1994; Boucher & Warrington, 1976; DeLong, 1992).

In the opening paragraphs of his seminal paper describing the syndrome of Autism, Kanner (1943) commented on the extraordinary memories of the children he was describing, particularly their ability to recite long lists of items or facts. Experimental studies have confirmed this observation. Hermelin and Frith (1971) demonstrated that children with Autism were as able as mental age controls to repeat back strings of words, and Prior and Chen (1976) demonstrated typical recall of both single items and lists in a visual memory task.

Another piece of the Autism-amnesia analogy concerns primacy and recency effects. O'Connor and Hermelin

(1967) were the first to note that primacy effects in list learning tended to be weaker than recency effects in Autism; these results were replicated by Boucher (1981). This pattern is also characteristic of adults with amnesia (Baddeley & Warrington, 1970). Hermelin and Frith (1971) attempted, unsuccessfully, to attenuate strong recency effects by composing sentences in which the beginning part of the word string was made up of meaningful sentence fragments, and the latter part was composed of random verbal material. The children with Autism continued to demonstrate strong recency and weak primacy effects even under these conditions. Deficient primacy but intact recency memory has been replicated more recently by Renner, Klinger, and Klinger (2000). As recency effects rely more purely on rote auditory mechanisms, whereas recall of the first part of a list requires further processing and encoding of the material, less developed primacy effects in Autism may be secondary to organizational and encoding impairments rather than to memory deficits per se, an issue to which we return later.

In a pioneering series of experiments, Hermelin, O'Connor, and colleagues found that the advantage in remembering meaningful over random material typically seen in normally developing individuals is not apparent in Autism; that is, individuals with Autism do not appear to use the syntactic and semantic cues that aid others in recalling material. For example, two studies demonstrated that children with Autism were just as capable of recalling random verbal material (e.g., unconnected words) as they were of remembering meaningful sentences (Hermelin & O'Connor, 1967; Hermelin & Frith, 1971). Later experiments clarified that children with Autism are not incapable of using semantic cues in recall but do appear to be less efficient in doing so and less likely to use this strategy spontaneously. Fyffe and Prior (1978) failed to replicate earlier results, finding that children with Autism recalled sentences significantly better than random word lists. Relative to controls, however, recall of sentences was deficient and recall of random material was adequate. Thus, although the group with Autism did appear to make use of meaning in recall, their advantage was not as great as in the mentally handicapped or typically developing control groups. Tager-Flusberg (1991) replicated this pattern, finding that recall of related and unrelated word lists was equivalent in the group with Autism; however, their memory for meaningful material was less efficient than that of controls.

Deficits in working memory have sometimes been found in Autism. Working memory is defined as the ability to maintain information in an activated, online state to guide

cognitive processing (Baddeley, 1986) and is thought to be subserved by the prefrontal cortex. An initial study found that subjects with Autism were significantly impaired relative to controls on working memory tasks but not on measures of short- and long-term recognition memory, cued recall, or new learning ability (Bennetto, Pennington, & Rogers, 1996). Later studies have been less consistent. In an investigation by Russell and colleagues (Russell, Jarrold, & Henry, 1996), a group with both Autism and mental retardation did not differ from matched controls on three measures of verbal working memory. In another study, no group differences were found in a higher-functioning sample, relative to matched comparison groups with Tourette's syndrome and typical development, on three tasks of working memory (Ozonoff & Strayer, 2001).

The evidence reviewed here suggests that Autism is not a primary disorder of long-term memory. Rather, difficulty appears to occur at the stage of encoding and organizing material. It is the overlay or additional requirement of higher-order processing that makes certain memory tasks difficult for people with Autism.

Language

In most children with Autism, impairment in language and communication is apparent early in life. Use of gesture to communicate is also notably restricted. Language does not always develop and, when it does, its onset is often delayed. For those who do speak, phonology and syntax are often consistent with mental age, but abnormalities in pragmatics, that is, language used to communicate socially (Tager-Flusberg & Anderson, 1991), are characteristic. Even mildly affected children show difficulty adapting their discourse to the listener's response or perspective and taking turns in conversation. Although high-functioning children with Autism are willing to engage in conversation, they often give no response, repeat questions and comments, and do not spontaneously elaborate; their conversational exchanges with others are marked by disjointedness, lack of reciprocity, and noncontextual utterances (Adams, Green, Gilchrist, & Cox, 2002; Capps, Kehres, & Sigman, 1998). Autism was at one time considered a disorder of language (Rutter, 1978), but more recent theories emphasize impairments in social cognition and attribute universal difficulties with pragmatic language to higher-order social information-processing deficits. We turn now to this large body of research.

Social Cognition

Problems perceiving faces and emotions have been documented in a number of studies. Using a crossmodal para-

digm in which subjects had to match affective and nonaffective auditory and visual stimuli, Hobson (1986) found that the group with Autism committed significantly more errors than controls matched on nonverbal IQ when matching affective material, but performed as well as controls on nonaffective crossmodal matching. Weeks and Hobson (1987) demonstrated that children with Autism preferred to sort faces by nonemotional attributes, such as hairstyles and accessories, than by emotional expressions. When required to sort faces by emotion, performance was significantly impaired relative to controls. Other researchers using different paradigms have replicated the finding that individuals with Autism are selectively impaired on affect-matching tasks, relative both to performance of comparison subjects matched on nonverbal IQ and to their own performance on nonaffective control tasks (Bormann-Kirschkel, Vilsmeier, & Baude, 1995; MacDonald et al., 1989).

A methodological issue was raised, however, suggesting that the role of verbal ability in emotion perception was not adequately controlled in early studies (Ozonoff, Pennington, & Rogers, 1990). If some verbal mediation is required to process affective information, then failure to match on verbal ability may account for group differences, rather than a primary deficit in emotion perception being responsible. Most initial studies matched control samples on nonverbal IQ alone. Subsequent investigations showed that when individuals with Autism were matched with control subjects on the basis of verbal ability, group differences were no longer apparent on emotion sorting, matching, and naming tasks (Braverman, Fein, Lucci, & Waterhouse, 1989; Davies, Bishop, Manstead, & Tantam, 1994; Hobson, Ouston, & Lee, 1988, 1989a; Loveland et al., 1997; Ozonoff et al., 1990; Prior, Dahlstrom, & Squires, 1990). Language ability and verbal IQ account for large amounts of variance in emotion perception scores, with intercorrelations in the .60 to .70 range (Fein, Lucci, Braverman, & Waterhouse, 1992). Capps, Yirmiya, and Sigman (1992) found deficits in recognizing only complex emotions, such as pride and embarrassment. Similarly, Adolphs and colleagues (Adolphs, Sears, & Piven, 2001) found no group differences in recognition of simple emotions but impairment when making social judgments, such as trustworthiness or approachability, from faces. These results suggest that there are a number of moderating variables that account for variance in emotion perception abilities in Autism. Group differences between samples with and without Autism may be secondary to linguistic, cognitive, pragmatic, or theory of mind deficits rather than reflecting a specific emotion-processing impairment. Research has also

demonstrated that emotion perception deficits are not specific to people with Autism, having also been documented in individuals with mental retardation (Hobson, Ouston, & Lee, 1989b), learning disabilities (Holder & Kirkpatrick, 1991), and Schizophrenia (Novic, Luchins, & Perline, 1984). It should be noted, however, that the emotion tasks used have all been poor approximations of naturalistic, real-world opportunities for emotion perception. Structured laboratory tests of this type are susceptible to compensation. Better tasks that measure basic, online affective processes, particularly those that develop early in life, are needed to fully test emotion-related hypotheses in Autism.

Several studies have also explored potential differences in more basic processes involved in understanding faces. As with emotion perception, results have been somewhat mixed, with some studies finding that identity matching and basic facial perception appear to be normal (Adolphs et al., 2001; Ozonoff et al., 1990; Volkmar, Sparrow, Rende, & Cohen, 1989), whereas other studies find deficits in these abilities (Boucher, Lewis, & Collis, 1998; Klin et al., 1999). New techniques that have only recently become available suggest that the mechanisms underlying face processing, regardless of accuracy, may be different in people with and without Autism. Recent eye-tracking and behavioral studies have demonstrated that individuals with Autism use an atypical and disorganized approach to viewing faces, including an unusual focus on nonfeature areas of the face, such as the mouth (Joseph & Tanaka, 2003; Klin, Jones, Schultz, Volkmar, & Cohen, 2002; Pelphrey et al., 2002), instead of the normal focus on the eyes (Emery, 2000). Dawson et al. (2002) used event-related potentials (ERP) to study response to familiar faces (i.e., their mother's) and unfamiliar faces in young children with Autism and matched controls. Only those with Autism failed to show a difference in ERP response to the familiar versus unfamiliar face, although they did show the expected response to familiar versus unfamiliar objects. Another important study, by Schultz et al. (2000), found that people with Autism and Asperger's syndrome use the inferior temporal gyrus, the part of the brain that normally makes sense of objects, when they look at faces and do not activate typical face-processing structures, such as the fusiform gyrus. These studies suggest that even when people with Autism can figure out what someone's eyes or face conveys, they do so in a different, possibly less efficient manner.

Another aspect of social cognition in Autism that has received a great deal of research attention is the theory of mind hypothesis, which became prominent in Autism research in the 1980s and 1990s and has been posited as able

to explain many characteristics of the disorder. Early studies demonstrated that children with Autism have specific difficulties in understanding states of mind such as false belief, ignorance, and second-order belief (beliefs about beliefs) in other people (Baron-Cohen, 1989a; Baron-Cohen, Leslie, & Frith, 1985). Deficits in theory of mind have been proposed to cause many of the social and language impairments that are part of Autism (Frith, 1989; Frith, Happé, & Siddons, 1994; Happé, 1993). The theory of mind account of Autism has been a very influential hypothesis that has generated a great deal of empirical research.

Recent functional imaging research has examined the neural foundations of theory of mind skills. Baron-Cohen and colleagues (1999) used fMRI to examine brain function while participants looked at pictures of eyes and made judgments about what mental states the eyes conveyed. They found that typical adults relied heavily on both the amygdala and the frontal lobes to perform this task. In contrast, adults with either high-functioning Autism or Asperger's syndrome used the frontal lobes much less than the normal adults and did not activate the amygdala at all when looking at the pictures of eyes. Instead, they used the superior temporal gyrus, which is not typically active during this task in people without Autism (Baron-Cohen et al., 1999). Happé et al. (1996) found that adults with Asperger's syndrome used different regions of the prefrontal cortex than typical controls when engaged in reasoning about mental states. A recent report found significantly less activation in the medial prefrontal cortex and the superior temporal sulcus, relative to controls, in adults with Autism Spectrum Disorders. Activation in the extrastriate cortex was high (and equivalent) in both groups, but the Autism spectrum group alone showed reduced connectivity between this region and the superior temporal sulcus, suggesting an information transfer bottleneck within this mentalizing network (Castelli, Frith, Happé, & Frith, 2002).

A limitation of the theory of mind hypothesis of Autism is that theory of mind skills do not begin to emerge in typical development until after symptoms of Autism are already present. Thus, they lack the developmental precedence necessary for causal explanatory power. Recent work has focused on potential precursors of later theory of mind development. One purported precursor is joint attention behavior, which typically emerges around the first birthday and involves sharing attention to an object with another person. It is evident usually through pointing, referential looking, and shared affect. Many studies have demonstrated a paucity or absence of joint attention behaviors in young children with Autism (Baron-Cohen, 1989b; Mundy & Sigman, 1989), and some have hypothesized that this is

the earliest sign of the failure to appreciate the minds of others exhibited by these children (Baron-Cohen, 1991; Mundy, Sigman, & Kasari, 1993).

Rogers and Pennington (1991) proposed that the symptoms of Autism might stem from impairment in another very early social process, that of imitation. Based on a theoretical model of early interpersonal processes developed by Stern (1985) and evidence that newborns are capable of imitating some body movements (Meltzoff & Moore, 1977), it has been proposed that infants and young children come to understand the behavior, subjective experiences, and mental states of other people through imitation, social mirroring, and affect sharing (Meltzoff & Gopnik, 1993; Rogers & Pennington, 1991). An early impairment in motor imitation could have cascading consequences that profoundly alter later social development. Many studies have documented imitation deficits in young children with Autism (e.g., Jones & Prior, 1985; Rogers, Hepburn, Stackhouse, & Wehner, 2003) and even in older, higher-functioning individuals with the disorder (Rogers, Bennetto, McEvoy, & Pennington, 1996). More work examining the developmental emergence and relationships among joint attention, imitation, other early social processes, and later theory of mind is needed.

Another limitation of the theory of mind hypothesis is that not all children with Autism lack a theory of mind. Studies have shown that higher-functioning individuals are often able to pass theory of mind tasks (Bowler, 1992; Ozonoff, Pennington, & Rogers, 1991). Nor are theory of mind deficits specific to Autism. A meta-analysis found significant theory of mind deficits in individuals with mental retardation as well as those with Autism (Yirmiya, Erel, Shaked, & Solomonica-Levi, 1998). Other linguistically handicapped children, including those who are deaf (Peterson & Siegal, 1995), may show theory of mind handicaps but not the other social and pragmatic impairments. Recent studies have failed to find deficits in the understanding of simple mental states, such as intentions, in young children with Autism (Carpenter, Pennington, & Rogers, 2001). These findings collectively have tempered early claims to have discovered the “core” psychological defect of Autism, as has the inability of this theory to account for the repetitive and stereotyped behaviors of Autism, as well as the cognitive strengths in visual-spatial processing that are often evident (Hughes, 2002). In recent years, there has been increasing debate and reevaluation of the theory, especially in terms of claims regarding its modularity or componential quality in brain development and dysfunction (Garfield, Peterson, & Perry, 2001; Tager-Flusberg, 2001). Questions about its relation to other

prominent neuropsychological deficits, such as executive function, have also been raised. We turn to this topic next.

Executive Function

Investigation of executive functions has been another active area of research in Autism. Beginning with Rumsey (1985), many studies have documented deficient performance on tests of executive function (EF). The dysfunction most often found is perseveration of behavior, that is, continuing to perform actions that are no longer appropriate or relevant given the context. An example of this is sorting by previously correct rules despite feedback that their strategies were incorrect (Prior & Hoffmann, 1990; Rumsey & Hamburger, 1988). Several research groups have found that executive deficits are apparent in Autism even relative to controls with other neurodevelopmental disorders (Ozonoff, Pennington, & Rogers, 1991; Szatmari, Tuff, Finlayson, & Bartolucci, 1990). In one study, performance on the Tower of Hanoi, a test of planning, correctly predicted diagnosis in 80% of subjects, whereas other neuropsychological variables (e.g., theory of mind, memory, emotion perception, spatial abilities) predicted group membership at no better than chance levels. Following the sample longitudinally, Ozonoff and McEvoy (1994) found that deficits on the Tower of Hanoi and Wisconsin Card Sorting Test (WCST) were stable over a 2.5-year period. Not only did EF abilities not improve during the follow-up interval, they showed a tendency to decline relative to controls over time. Shu, Lung, Tien, and Chen (2001) reported significant deficits on WCST performance in a sample of 26 Taiwanese children with Autism, relative to matched controls. Because these children were raised in a completely different culture and environment from the Western children who participate in most EF studies, the authors suggested that executive dysfunction may be a core impairment in Autism. In a review of the EF literature, Pennington and Ozonoff (1996) reported that 13 out of the 14 studies existing at the time of publication demonstrated impaired performance on at least one EF task in Autism, including 25 of the 32 executive tasks used across those empirical studies. The magnitude of group differences tended to be quite large, with an average effect size (Cohen's *d*) across all studies of .98, marked by especially large effect sizes for the Tower of Hanoi ($d = 2.07$) and the WCST ($d = 1.04$). Recently, significant group differences on the Intradimensional/Extradimensional Shift task of the Cambridge Neuropsychological Test Automated Battery were found in a very large sample of individuals with Autism and matched controls recruited from the Collaborative Programs of Excellence in Autism network funded by the National Institutes

of Health (Ozonoff et al., 2004). This work was important in replicating the flexibility impairment of Autism across samples collected at seven independent sites in individuals ranging in age from 6 to 47 years.

Two research groups have tested age-related EF development in very young children with Autism. McEvoy, Rogers, and Pennington (1993) studied preschool-age children with Autism (mean age = 5 years) and matched developmentally delayed and typically developing control groups. Significant group differences were found on the spatial reversal task, a measure of flexibility developed for infants and nonhuman primates, but no group differences were evident on three other EF measures. It was suggested that these tasks may have been less developmentally appropriate for the sample. However, in another investigation by the same research team (Griffith, Pennington, Wehner, & Rogers, 1999) studying even younger preschool children with Autism (mean age = 4 years), there were no differences in performance on any of eight executive tasks (including the spatial reversal task), compared to a developmentally delayed group matched on chronological age and both verbal and nonverbal mental age. Likewise, in a larger study of even younger children with Autism (mean age = 3 years), Dawson et al. (2002) reported no significant differences on six EF tasks (again including spatial reversal), relative to developmentally delayed and typically developing control groups matched on mental age. This work raises the possibility that EF deficits in children with Autism emerge with age and are not present (at least relative to other samples with delayed development) early in the preschool range. Because executive functions are just beginning to develop during the early preschool period in all children, a relative lack of variance across groups may explain this apparent developmental discontinuity. Differences in the way EF is measured at different ages may also contribute to this finding. The executive tests that have been administered to very young children with Autism do not require the same use of arbitrary rules (Biro & Russell, 2001) and social feedback (Ozonoff, 1995) that those given to older individuals do. If these features are central to the EF performance deficits of Autism, then the discontinuity between earlier and later development may be due simply to measurement differences. Further work, particularly longitudinal research, is needed to examine when during development specific executive difficulties emerge and what their developmental precursors may be.

Another recent research trend has been to study the relationships between EF and other cognitive and social-cognitive processes. The explanatory power of executive dysfunction for Autism would be greatest if individual dif-

ferences in EF predicted variations in other impairments or in symptoms of Autism. In fact, one of the initial appeals of the EF hypothesis of Autism was its apparent ability to account for the repetitive and stereotyped behaviors of the disorder (Turner, 1997), something that the theory of mind and other neuropsychological models of Autism had failed to explain (Hughes, 2002). Empirical support for a relationship between executive dysfunction and repetitive behaviors is mixed. Turner reported that perseveration on a set-shifting task was correlated with more primitive stereotyped behaviors, such as hand flapping, and impoverished generativity was correlated with "higher-level" repetitive behaviors such as circumscribed interests. In contrast, South, Ozonoff, and McMahon (in press) found no significant correlations between any category of repetitive behavior and any EF variable. For example, the correlations between the number of perseverations on the WCST and various forms of repetitive behavior ranged from a low of $r = -.03$ for lifetime history of circumscribed interests to a high of $r = .16$ for lifetime history of unusual obsessions with objects. This sample was significantly older (mean age = 14 years) and more intellectually capable (mean VIQ = 111) than Turner's sample, so direct comparisons are difficult and further research is clearly needed.

Other work has explored the relationship between executive function and theory of mind skills. In a study designed to examine theory of mind and strategic deception abilities (Russell, Mauthner, Sharpe, & Tidswell, 1991), children with Autism were taught to play a game in which they competed with an experimenter for a piece of candy. The candy was placed in one of two boxes with windows that revealed the contents of the box to subjects but not to the experimenter. The objective of the task was to fool the experimenter into looking for the candy in the empty box. It was explained that the strategy of pointing to the empty box would be successful in winning the candy, whereas pointing to the box that actually contained the chocolate would result in losing it. Even after many trials, the subjects with Autism were unable to point to the empty box, despite the consequences of this strategy. Russell et al. first attributed these results to a perspective-taking deficit that caused an inability to engage in deception. In a follow-up study, Hughes and Russell (1993) demonstrated that significant group differences remained even after the element of social deception was removed from the task. Subjects were simply instructed to point to the empty box to get the candy. Even with no opponent present, the subjects with Autism persisted in using the inappropriate strategy. On the basis of these results, Hughes and Russell reattributed the pattern of performance to a deficit in disengaging

from the object and using internal rules to guide behavior, rather than to a social or perspective-taking dysfunction. This work led the way for several other studies that explored the hypothesis that some degree of executive control is necessary for successful performance on theory of mind tasks and, by extension, for the development of theory of mind (e.g., Russell, Saltmarsh, & Hill, 1999).

The opposite hypothesis, that some level of social awareness is necessary for executive function, has also received support. In the WCST, for example, feedback is provided by the examiner after each card is sorted; successful set shifting requires using this feedback to alter behavior. If, however, feedback supplied in a social context is less salient or more difficult to process for people with Autism, they may perform poorly on EF tasks for primarily social reasons. A few studies have contrasted performance on executive tests when they are administered in the traditional manner, by human examiners, to performance when they are administered by computer. Ozonoff (1995) reported that the WCST was significantly easier for individuals with Autism when it was given by computer, with group differences considerably smaller in the computer administration than the human administration conditions. In the group with Autism, the number of perseverations was cut in half on the computerized version of the task, but performance did not differ across conditions in the typically developing control group (Ozonoff, 1995). This finding has been replicated by two independent research groups (Griffith & Pennington, 2003; Pascualvaca, Fantie, Papageorgiou, & Mirsky, 1998). This suggests that the format of the executive task, particularly the nature of the feedback (social versus nonsocial), may have a much greater impact on performance for people with Autism than has been appreciated. Thus, it has been difficult to tease apart the relative primacy of executive function and mentalizing or other social deficits in the chain of cognitive impairments that are involved in Autism.

It has also become clear that other non-EF skills, such as language and intelligence, may contribute to EF deficits. Liss et al. (2001) gave a battery of EF tests to children with high-functioning Autism and a control group of children with language disorders. The only group difference, more perseverative errors on the WCST by the Autism group, disappeared when Verbal IQ was statistically controlled. Ozonoff (Miller & Ozonoff, 2000; Ozonoff & McEvoy, 1994; Ozonoff & Strayer, 2001) has also identified significant relations between IQ and EF performance in people with Autism. And Perner and Lang (2002) reported a pair of large studies of typically developing preschool children

in which the correlation between EF and a language task was just as high as its correlation with a false belief task.

Finally, it is apparent that EF deficits are not specific to Autism but are found in many other disorders, including ADHD (Shallice et al., 2002), Obsessive-Compulsive Disorder (Spitznagel & Suhr, 2002), and Schizophrenia (Bustini et al., 1999). Thus, the EF account of Autism has failed, like the theory of mind account, as a grand cognitive theory of Autism. EF deficits are not specific to Autism, universal in individuals with the condition, nor precedent in development.

Central Coherence

A third theory put forth as an integrative explanation for the pattern of symptoms seen in Autism is that of weak central coherence (Frith & Happé, 1994). This theory suggests that the core psychological impairment in Autism is the failure to process information in context. The information processing of typically developing individuals is motivated by a “drive” to achieve higher-level meaning and a preference for global processing. Frith (1989) first introduced the idea that it is this drive for central coherence that is missing in Autism, resulting instead in detail-focused processing. Central coherence theory predicts that people with Autism will perform poorly on tasks that require integration of constituent parts into coherent wholes, but will perform normally (or even in a superior fashion) on tasks that require a focus on detail or “local processing.” They should also show preserved or enhanced performance on tasks in which the typical tendency to use contextual information actually interferes with performance, because central coherence theory predicts that people with Autism would be relatively impervious to context effects. An essential feature of central coherence theory is that the detail orientation of Autism is a consequence of a deficit in global processing.

Central coherence theory has intuitive appeal, as it appears to explain both the neuropsychological deficits and the particular cognitive strengths of people with Autism (Happé, 1999). It also has potential to account for some behavioral symptoms of the condition that other theories have failed to explain, such as repetitive and stereotyped behaviors. For example, weak central coherence could explain the focus on technicalities and trivia seen in the circumscribed interests of people with Autism Spectrum Disorders, as well as their insistence on sameness in the environment.

Several studies have supported the central coherence theory of Autism. Frith and colleagues found that children

with Autism were significantly more accurate in discovering figures embedded in complex pictures than controls matched on mental and chronological age (Shah & Frith, 1983). This research team also found evidence that weak central coherence played a role in the strong performance of people with Autism on the Wechsler Block Design subtest (Shah & Frith, 1993). They found that presegmenting the designs significantly improved performance for participants without Autism (both those with typical development and those with mental retardation), presumably because of the strong tendency to process the unsegmented designs as a gestalt. The performance of people with Autism, however, was not enhanced by presegmentation, suggesting that this group had a natural tendency to see the stimuli in terms of parts rather than as a whole and did not need the parts to be explicitly highlighted. Other supportive evidence of central coherence deficits in Autism came from verbal tasks. Several studies have shown that individuals with Autism fail to use sentence context to determine the correct pronunciation of homographs, words with one spelling but two meanings (e.g., *lead*; Frith & Snowling, 1983; Happé, 1997; Jolliffe & Baron-Cohen, 2000). In global-local tasks, in which large stimuli (usually either letters or numbers) are composed of smaller similar stimuli (also letters or numbers), people with Autism show an advantage at identifying the local details that slow and make less accurate identification of global patterns (Rinehart, Bradshaw, Moss, Brereton, & Tonge, 2000).

Later studies have not fully confirmed these results, however. Several subsequent investigations have used the Embedded Figures Test, with one study finding no superiority in accuracy (Ozonoff et al., 1991), another failing to replicate the accuracy results but demonstrating significantly faster reaction time on the part of people with Autism Spectrum Disorders (Jolliffe & Baron-Cohen, 1997), and a third failing to find superiority in either accuracy or reaction time (Rodgers, 2000). A prediction of central coherence theory is that there should be little difference in performance when the context in which the shape is embedded is meaningful or nonmeaningful, as the deficit in global processing leads to little or no encoding of context. Two studies used adaptations of the Embedded Figures Test in which the meaningfulness of the context was manipulated. Both investigations found that the performance of participants with Autism was affected by the contextual information in the same manner as the controls (Brian & Bryson, 1996; Lopez & Leekam, 2003). Brian and Bryson also examined memory for the contextual information and found that it was as good as

controls, demonstrating that the context *was* being actively processed and encoded.

Mixed results have been obtained on global-local tasks as well. Later investigations have failed to replicate the superiority at identification of local targets (Rodgers, 2000) or the deficiency of processing global configurations (Mottron, Burack, Stauder, & Robaey, 1999; Ozonoff, Strayer, McMahon, & Filloux, 1994). In an elegant experimental design, Plaisted, Swettenham, and Rees (1999) demonstrated that administration procedures have large effects on performance and could account for the inconsistent pattern of results across studies. They found normal global processing in Autism using a selective attention procedure in which participants focused on only one level (either global or local) for long blocks of stimulus presentation, but a local advantage in Autism during a divided attention procedure in which participants had to shift between global and local levels from trial to trial. This suggests that difficulty switching attention (an executive or attentional deficit) may be part of poor performance and argues against a pure central coherence explanation for the deficit found on such global-local tasks.

Findings have been similarly inconsistent using other paradigms. Happé (1996) first reported that individuals with Autism were much less likely than control participants to succumb to visual illusions, which are dependent on context. However, Ropar and Mitchell (1999) failed to replicate this nonsusceptibility, using the same illusions employed in the Happé study. They also reported low and nonsignificant correlations among visual illusion nonsusceptibility and several visuospatial tasks also thought to measure weak central coherence (e.g., Block Design, Embedded Figures Test; Ropar & Mitchell, 2001), further questioning the construct and its selective association with Autism.

These nonreplications, particularly the repeated findings that individuals with Autism do appear to use context and perceive gestalts (Brian & Bryson, 1996; Lopez & Leekam, 2003; Mottron et al., 1999; Ozonoff et al., 1994; Ropar & Mitchell, 1999), have suggested a modified version of central coherence theory. It has been proposed that the cognition of people with Autism does involve some "local bias" or preference for detail-oriented processing but that this is not due to a deficit in global processing. Several recent investigations have supported this notion. Plaisted and colleagues (Plaisted, Saksida, Alcantara, & Weisblatt, 2003) found that a group of participants with Autism demonstrated enhanced ability to identify individual features of a stimulus but also were as good as controls

at integrating these features to see the significance of the configuration of the features.

In a final study of interest, weak central coherence was found to be more common in a group of adolescents with high-functioning Autism than developmental norms for the tests would predict, but was far from universal, with half of those with Autism demonstrating performance across several tests indicative of *strong* central coherence (Teunisse, Cools, van Spaendonck, Aerts, & Berger, 2001). Given the mixed results of studies of weak central coherence, its status as a core neuropsychological impairment of Autism is currently uncertain (Hoy, Hatton, & Hare, 2004).

Conclusion

Although aspects of the central coherence theory describe well the cognition of Autism, it has fared similarly to the executive function and theory of mind accounts in failing as a grand theory capable of organizing the behavioral and cognitive strengths and weaknesses of Autism within one unifying theory. So, we do not have a convincing single deficit theory of Autism. Part of the puzzle of this disorder is that it involves multiple neuropsychological deficits, but at the same time there is specificity to the profile of strengths and weaknesses. There are several broad solutions to this puzzle, but we do not yet know enough to distinguish among them. One possibility is a developmental cascade model (e.g., Fein, Pennington, Markowitz, Braverman, & Waterhouse, 1986; Rogers & Pennington, 1991), in which one early deficit disrupts the enculturation through which many distinctive human cognitive capacities develop. Another is that there are neuropsychological subtypes of Autism, each with its own primary deficit. A third possibility is that the notion of a single primary neuropsychological deficit is too simple, and that what is required is two or more interacting primary deficits. A final possibility is that the seemingly disparate multiple deficits that have been observed all share some general underlying cognitive characteristic, such as complex information processing, and it is the deficit in that cognitive process that is primary.

Evaluating these possibilities in light of the empirical findings just reviewed, it remains possible that some early developing aspect of basic affective or interpersonal processing is the primary deficit in infants with Autism and that this deficit “unhooks” these infants from normal socialization, thus producing a cascade of deficits in the domains reviewed here: attention, memory, language, social cognition, executive functions, and central coherence. Unfortunately, our knowledge of affective processes in typical

infants, especially infants with Autism, is very sparse, so it is difficult to critically examine this hypothesis at the present time. None of the three other possible solutions to the puzzle of the neuropsychology of Autism—subtypes with their own primary deficits, multiple interacting deficits, or a deeper core cognitive deficit—can be clearly rejected at this point. The evidence reviewed in this section suggests it is unlikely that deficits in memory will be on the list for subtype or multiple interacting deficit causal theories of Autism. It is possible, although not probable, that difficulties in attention shifting, theory of mind, imitation, affective processes, executive functions, and central coherence may define different subtypes of Autism. It is more plausible, but equally undetermined, that some or all of these impairments are components of a set of interacting deficits that as a configuration are primary to Autism. Finally, we turn to our fourth possible solution to the puzzle, that of a deeper core cognitive deficit.

Minshew (Minshew, Goldstein, & Siegel, 1997) has proposed that the central cognitive deficit in Autism is one of complex information processing. Any neuropsychological task, be it perceptual, spatial, verbal, or motor, that requires less information processing will be spared, according to this account, and those that require higher-order information processing will be impaired. The review of the Autism literature across many neuropsychological domains appears to support this theory. We have summarized the relative sparing of simple language processes (e.g., phonology, syntax), simple executive functions (e.g., inhibition), simple attentional processes (e.g., selective and focused attention), and simple memory functions (e.g., rote and recognition), with complementary dysfunction in each of these domains at the level of more complex processes (e.g., language pragmatics, cognitive flexibility, abstraction, attention shifting, working memory). The complex information-processing theory is also compatible with recent neurological findings of enlarged brains (Courchesne et al., 2003) with increased number of cortical columns of reduced size and density (Casanova et al., 2002), which could significantly disrupt neural networks, increase noise in the computational system, and lower efficiency of information processing (Casanova et al., 2002).

There is an important conceptual challenge for this theory, however, which is the need for a more detailed and principled account of what makes a cognitive task complex or not. Does complexity just equal difficulty? Chapman and Chapman (1973) argued a long time ago that many demonstrations of apparently specific cognitive deficits in Schizophrenia did not equate the experimental and compar-

ison tasks for difficulty. It is not too surprising that subjects with an extreme neurodevelopmental disorder like Schizophrenia would perform differentially worse on difficult cognitive tasks. A similar pattern would be expected in mental retardation syndromes and in Autism. So, for the complex information-processing theory to work, we need an explicit definition of cognitive complexity that is derived independently of the empirical results in Autism, yet explains the specific pattern of cognitive strengths and weaknesses found in Autism, which differ from those found in Schizophrenia or mental retardation.

A second challenge to the complex information-processing theory of Autism is that it does not adequately explain the very early symptoms of Autism that are often apparent before the first birthday (Osterling & Dawson, 1994). Autism is particularly interesting because impairments in very basic interpersonal processes coexist with spared abilities in certain cognitive domains, such as memory and visual-spatial processes. The complex information-processing theory cannot explain why a 2-year-old with Autism can put together puzzles at a 3-year mental age level but is not able to point, a developmentally simpler skill normally apparent by 1 year of age.

Recent genetic advances make it clear that a number of interacting genes may be needed for the development of Autism. It is implausible that all genes (and other potential environmental factors) confer susceptibility for a single specific neuropsychological deficit. Moreover, such modular hypotheses are unable to account for the variations across the spectrum of Autism in severity and pattern of symptoms and deficits. These variations make subtypes and multiple deficit theories more likely, but more work is needed to identify the relevant deficits. Although research on the neuropsychology of Autism has been very active, it is far from definitive at this point. Like the blind men describing the elephant, the theories proposed depend largely on the characteristics of the participants and the neuropsychological domains being studied. Researchers who study young children focus on early interpersonal deficits; those who study older and higher-functioning individuals focus on cognitive impairments. No model accounts for everything. A major test of any viable future model will be its ability to explain early appearing infant symptoms. Research on the very early development of infants at family risk for the disorder will help identify such deficits, as will a more careful dissection of the typical development of early social cognition. Until we have a better model of typical very early social-emotional development (prejoint attention), answers to the Autism puzzle may remain elusive.

In the next section, we apply the neuroscientific model of developmental psychopathology to a very different condition, Posttraumatic Stress Disorder, and see how the four levels of explanation, particularly the neuropsychological model, fare.

POSTTRAUMATIC STRESS DISORDER

This section of the chapter reviews the literature on Posttraumatic Stress Disorder (PTSD) as it pertains to the four levels discussed earlier. Although once considered an adult disorder, PTSD is highly relevant to the field of developmental psychopathology, as it is a relatively common consequence of child abuse, which affects at least 15 of every 1,000 children in the United States (Daro & Donnelly, 2002). PTSD was selected as the focal disorder for this section because it presents several interesting and complex challenges for the neuropsychological model of developmental psychopathology.

First, PTSD is unique among mental disorders in that, by definition, it is the result of a specific etiological-level environmental event (e.g., a trauma). In this respect, PTSD is very different from Autism, which is a highly heritable disorder for which environmental risk factors have yet to be identified. But, as is discussed later, there are also genetic influences on PTSD, which represents a relatively simple example of a diathesis-stress model of developmental psychopathology, with a defined stressor. Second, PTSD is a disorder involving stark contrasts in neuropsychological symptoms. Vivid, intrusive, and arousing memories present alongside amnesia, forgetting, and numbing. Symptoms of dissociation also may be part of the disorder. Third, other conditions, including depression and Generalized Anxiety Disorder, frequently are comorbid with PTSD, making syndrome definition challenging.

As described in more detail later, reasonable conceptual neuropsychological models of PTSD have been developed. There has been tremendous growth in empirical work to explain the neurobiology of anxiety, fear, and stress. So another reason PTSD was chosen for this section is that much of this recent neuroscience research is relevant to PTSD and offers new information about the brain mechanisms involved in the disorder. In fact, some researchers (see LeDoux, 2002, p. 294) have chosen to focus on PTSD because, at the neuropsychology level, the disorder offers the clearest available model of classical conditioning in a mental disorder (Pitman, Shalev, & Orr, 1999). Furthermore, a

merger between the brain and neuropsychological levels appears to be occurring in studies of PTSD.

Pennington (2002) states that the four-level framework is not intended as a grand theory of any disorder but as an organizing structure potentially capable of incorporating and assimilating new discoveries at each level. The neuropsychological level, in particular, is likely to undergo significant changes as a consequence of advances in computational and affective neuroscience. A comprehensive review of factors involved in the etiology, neurobiology, and neuropsychology of PTSD offers an opportunity to explore these propositions. As before, we have chosen to organize this section with symptoms first because it is easier to read, although, particularly in the case of PTSD where the neuropsychology of the condition is well understood, this sequence downplays the centrality of the neuropsychological domain in bridging the mind-body gap.

Level 4: Symptoms, Diagnostic Definitions, and Epidemiology

Although military psychiatrists have long recognized that exposure to war-related atrocities can produce persistent stress symptoms in previously well-adjusted individuals, it was not until after the Vietnam War that Posttraumatic Stress Disorder was included in the *Diagnostic and Statistical Manual of Mental Disorders* (APA, 1980). Members of the *DSM-III* task force eventually agreed to the inclusion of PTSD as it became clear that a similar syndrome occurred in survivors of other traumas, including rape, abuse, natural disasters, and concentration camp confinement.

DSM-IV (APA, 1994) broadened the definition of PTSD, creating what some have called “bracket creep” in the boundaries of the syndrome (McNally, 2003). To meet the *DSM-IV* diagnostic criteria for PTSD, individuals must be exposed to a traumatic event in which they experience or witness events that involve the threat of death or serious damage to the integrity of self or other, and their response must involve intense fear, helplessness, or horror. Thus, to be diagnosed with PTSD, one need not actually be involved in the trauma: It is enough to be either vicariously involved or to be horrified about what has happened to others. *DSM-IV* stipulates that in children, this intense reaction may be expressed by disorganized or agitated behavior.

Three symptom clusters define PTSD: reexperiencing, avoiding, and increased arousal. To meet diagnostic criteria, the individual must have one symptom from the first cluster that indicates that the traumatic event is persistently reexperienced in either intrusive and distressing recollections of the event, in recurrent and distressing dreams of the

event, in acting or feeling that the event is reoccurring, in psychological distress at exposure to cues that symbolize the event, or in physiologic reactivity to these cues. *DSM-IV* notes variations in the first three of these for young children, such that reexperiencing may be acted out in repetitive play, nightmares need not have content specific to the trauma, and trauma-specific reenactments may occur.

The individual must also experience three or more symptoms related to avoidance and general numbing of responsiveness. These include efforts to avoid thoughts, feelings, or conversations associated with the trauma; efforts to avoid activities, places, or people that arouse recollections of the trauma; amnesia for important aspects of the trauma; diminished interest or participation in significant activities; feelings of detachment and estrangement; restricted range of affect; and a sense of foreshortened future. Two or more symptoms of hyperarousal must also be present to meet PTSD criteria. These include difficulty falling or staying asleep, irritability, concentration problems, hypervigilance, and/or an exaggerated startle response.

Two final criteria for the PTSD diagnosis are that the symptoms last at least 1 month and cause functional impairment. Symptoms may be defined as acute or chronic depending on whether they are present for less or more than 3 months. PTSD onset is viewed as delayed if it occurs 6 months or more after the trauma. One of the distinctive symptoms of PTSD is the repetitive experiencing of traumatic and richly detailed memories or flashbacks that intrude into consciousness and/or dreams. These memories may be highly detailed and laden with affective content. Although some degree of reexperiencing a trauma is relatively common, in PTSD these symptoms do not fade over time.

DSM-III-R (APA, 1987) first recognized that PTSD could develop in children as well as adults. Initially, diagnostic criteria for children were simply a downward extension from observations made in adults. In *DSM-IV-TR* (APA, 2000), there are now specific descriptions of how symptoms may manifest in children. A child’s response to a traumatic event may be manifested as disorganized or agitated behavior rather than intense fear or horror, for example. It is also noted that children may represent the trauma through repetitive play and that frightening dreams may occur without content that is recognizably related to the trauma.

A common trauma leading to PTSD in childhood is chronic and/or severe physical, emotional, or sexual abuse. Child maltreatment represents the greatest failure of the environment to provide the expectable experiences that are vital to normal child development (Cicchetti & Lynch,

1995). As we summarize later, trauma and abuse can affect attachment, interfere with and/or bias information processing, dysregulate mood, and enhance the stress response throughout life (Maughan & Cicchetti, 2002; Teicher et al., 2003). Despite recent advances in the conceptualization of pediatric PTSD, more work to understand the nature and extent of stress reactions in children is needed (Lonigan, Phillips, & Richey, 2003; Yule, Perrin, & Smith, 2001). For example, it is not well understood why symptoms of PTSD in chronically abused children often are not as prominent as those following other traumas and may be obscured by other social, cognitive, and behavioral problems (van der Kolk, 2003).

Epidemiology

Community-based studies of PTSD show a lifetime prevalence of approximately 8% of the adult population (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). At-risk individuals, including combat veterans, victims of crime, and victims of natural disasters, face a much higher prevalence rate, with estimates ranging from 3% to 58%. Women are twice as likely as men to develop PTSD (Kessler et al., 1994).

Traumatic events faced by men, women, and children tend to differ, as do those experienced by individuals from different ethnicities and social classes. Pynoos, Steinberg, and Wraith (1995) have developed a typology of reported traumatic exposures experienced by children and adolescents. These include small- and large-scale natural disasters, accidents, intra- and extrafamilial violence, and life-threatening illnesses and medical procedures. Terrorist attacks, including those occurring on September 11, 2001, offer a new class of traumatic events for study (North, 2004). Traumatic stress in school-age children and adolescents is a complex phenomenon involving a wide variety of emotional, cognitive, perceptual, sensory, and physiological experiences (Pynoos, Steinberg, & Piacentini, 1999).

The prevalence of PTSD in children in the community is not known. One estimate, based on a study of 386 older adolescents, is that 6.3% met the *DSM-III-R* lifetime criteria for PTSD (Reinherz, Giaconia, Lefkowitz, Pakiz, & Frost, 1993). Widely varying rates of PTSD have been found in children exposed to extreme stressors. For example, Terr (1979) reported that the incidence of psychic trauma was 100% after the Chowchilla bus kidnapping. Yule, Udwin, and Murdoch (1990) found that approximately 50% of the survivors of the sinking of the cruise ship *Jupiter*, which had more than 400 British schoolchildren on board, met the criteria for PTSD in the 1st

year following the incident. Green et al. (1991) reported that of the 179 children age 2 to 15 examined after the Buffalo Creek disaster, 37% received probable PTSD diagnoses based on a retrospective review of records. A consensus is emerging that approximately one-third of children may develop PTSD following traumatic events (Breslau, Davis, Andreski, & Peterson, 1991; Resnick, Kilpatrick, Dansky, Saunders, & Best, 1993; Yule & Udwin, 1991). Factors such as type of trauma, extent of exposure, age, gender, level of premorbid functioning, social support, and coping style appear to moderate the risk of developing PTSD symptoms after exposure to a traumatic event (Lonigan et al., 2003; Pine & Cohen, 2002).

Several studies have found that persons with PTSD and PTSD symptoms are at risk for a variety of other problems later in life, including suicidality, premature death, sexual revictimization, and somatization symptoms (Lonigan et al., 2003). About 80% of adults with PTSD also have a comorbid diagnosis of alcohol abuse, depression, Generalized Anxiety Disorder, or Panic Disorder. It is unclear, however, whether these conditions are risk factors for PTSD or results of PTSD, or whether PTSD and these conditions are each related to some third factor (Pennington, 2002).

Level 1: Etiology—Genes, the Environment, and Transactions

PTSD is a disorder whose etiology appears best explained by a diathesis-stress model. The precipitant of PTSD is fairly clearly defined by the diagnostic criteria themselves, and this makes it a clean example of a disorder caused in part by an environmental stressor. To understand the diathesis part of the etiologic model, we examine genetic factors contributing to the vulnerability to develop PTSD and, in doing so, touch on etiological factors implicated in other anxiety disorders. Molecular genetics, behavioral genetics, and animal models are discussed, as well as selected environmental factors and transactions between genes and the environment. As will become evident, there is a close relationship between genes and brain development. Thus, some of the effects discussed in this section are further elaborated in later parts of the review concerning the brain level.

Genetics

Molecular and behavioral genetics methods have been applied to the study of anxiety disorders. Efforts to discover genes specific to PTSD, like those to locate putative genes

responsible for Panic Disorder, phobias, and Obsessive-Compulsive Disorder, have proven unsuccessful. Molecular genetics work has been hampered, in part, by difficulty drawing boundaries between different anxiety disorder phenotypes and nonclinical anxiety that is part of typical development (Smoller, Finn, & White, 2003). There have been few published molecular genetic studies of PTSD. Comings, Muhleman, and Gysin (1996) reported a potential association between a TaqI DRD2 receptor polymorphism and PTSD, but this was not replicated in a subsequent study (Gelernter et al., 1999).

Given that PTSD requires an external trigger, it is difficult to perform family studies of the disorder. Davidson and colleagues (Davidson, Tupler, Wilson, & Connor, 1998) found that relatives of individuals with both PTSD and depression were more likely to suffer from depression. However, having PTSD alone was not associated with an increased family risk for either disorder.

Several studies based on a group of more than 4,000 twin pairs consisting of Vietnam veterans and their twins have provided strong evidence for both environmental and genetic influences on the development of PTSD (Goldberg, True, Eisen, & Henderson, 1990; True et al., 1993). In MZ twin pairs discordant for heavy combat exposure, Goldberg et al. found that individuals exposed to war trauma were 9 times more likely to have PTSD than cotwins not serving in Vietnam. After controlling for combat exposure, True and colleagues found that heritabilities for PTSD symptoms were 13% to 30% for reexperiencing symptoms, 30% to 34% for avoidance symptoms, and 28% to 32% for arousal symptoms.

Inherited personality traits also may mediate the response to trauma. Several studies have found that neuroticism and extraversion, both of which are moderately heritable, are related to who develops PTSD after a trauma and to the severity of the symptoms (see Fauerbach, Lawrence, Schmidt, Munster, & Costa, 2000). Emotionality, conceptualized as neuroticism, anxiety, electrodermal lability, and lowered habituation, appears to be an important moderator of how conditionable an individual is to fear responses (Pitman et al., 1999). Anxiety sensitivity, a psychological construct incorporating concern over anxiety-related sensations, also is highly heritable (Stein, Jang, & Livesley, 1999).

Animal studies indicate that individual differences in reactivity to stress and novelty are partly genetically mediated (Sanchez, Ladd, & Plotsky, 2001). For example, in squirrel monkeys separated from their mother, cortisol levels measured 1 day after separation show significant post-

natal rearing effects, whereas by 3 to 7 days, the effects of separation are minimal and heritability is significant (Lyons, Martel, Levine, Risch, & Schatzberg, 1999). In further support of the heritability of vulnerability to anxiety disorders, an animal model using mice bred to exhibit characteristics of learned helplessness showed that animals with this genetic predisposition respond differently to trauma than mice not bred for these characteristics. Specifically, exposure to stress produced physiologic symptoms of analgesia, cognitive deficits, and hypothalamic-pituitary-adrenal (HPA) dysregulation (King, Abend, & Edwards, 2001). HPA dysregulation, which is hypothesized to be an important component in PTSD and affective and anxiety disorders, is explored in more detail in the brain mechanisms section.

Environment and Transactions

Numerous factors can be considered part of the environment. As discussed earlier, the most central environmental factor to PTSD is the trauma. Here we examine the role of other environmental factors, particularly the contribution of parenting behavior, to the child's experience of stress. Research suggests that parents and caretakers greatly influence the child's experience of trauma. In situations of imminent danger, parental reactions of extreme anxiety may exacerbate the child's fearfulness (Pynoos et al., 1999). Parents can play a role in maintaining anxious behavior in their children after traumatic stress by modeling and reinforcing anxious and/or avoidant behavior and not encouraging the development of coping behaviors (Hudson, Kendall, Coles, Robin, & Webb, 2002). In general, the presence of a caring adult mitigates the effects of childhood stress (Masten, Best, & Garmezy, 1990). In the opposite scenario, when a parent is the agent of the trauma, as in child maltreatment, there is a serious challenge to the species-typical environmental transactions that play a critical role in the emergence and timing of normal developmental processes (Cicchetti & Lynch, 1995; Cicchetti & Toth, 2000).

At the biological level, animal studies have shown that typical variations in maternal care "program" the expression of genes regulating behavioral and endocrine stress responses in offspring. Hippocampal synaptic development is affected by maternal care such that long-term potentiation, important in the processes of learning and memory, may be enhanced. Furthermore, characteristics of maternal care influence oxytocin receptor gene expression in female offspring, and this appears to form the basis of intergenerational transmission of individual differences in stress reactivity (Meaney, 2001).

To summarize, the etiology of PTSD appears to require both a stressor (by definition) and a diathesis or predisposition that may be biologically and/or environmentally mediated.

Level 2: Brain Mechanisms

Research over the past decade has produced tremendous advances in our understanding of the pathophysiology of negative emotional states, including those associated with stress and fear. This proliferation of work is due to several factors, including the development of compelling animal models and of noninvasive structural and functional neuroimaging techniques for humans.

Traumatic stress is hypothesized to affect complex and interrelated neurochemical and structural aspects of brain development and functioning, including the HPA axis, neurotransmitter systems, limbic structures (particularly the hippocampus and amygdala), and psychophysiologic responses. As highlighted next, results of animal and human brain studies require integration into the evolving literature on the neuropsychology of PTSD.

The Hypothalamic-Pituitary-Adrenal Axis

Stress early in life is related to long-term alterations in bodily systems that mediate the stress response. In mammals, the HPA axis (sometimes referred to as the limbic-hypothalamic-pituitary-adrenal or LHPA axis, given its connections with the limbic system) is the major neuroendocrine stress response system. The HPA axis is activated in stressful conditions to mount the organism's "fight or flight" response. Corticotropin-releasing factor (CRF) is released from the hypothalamus. This stimulates the release of adrenocorticotropin hormone (ACTH) from the pituitary, which, in turn, causes glucocorticoids (cortisol in humans) to be released from the adrenal glands. This process has a negative feedback effect on the pituitary, hypothalamus, and hippocampus.

Persistent changes in CRF in the central nervous system are hypothesized to mediate the association between stressful experiences and the development of mood and anxiety disorders. It has been suggested that the relationship between early life stress and later psychiatric disorders is related to persistent elevations in CRF neurotransmission and alterations in other neurotransmitter systems. Animal studies have supported the relationship between CRF and negative affect. In the laboratory, administration of CRF produces effects that mimic stress, depression, and anxiety, including increases in heart rate and

arterial pressure, disruption of sleeping, and suppression of exploratory behavior (Heim & Nemeroff, 1999). CRF also acts on the central nervous system to trigger additional neurochemical stress responses, such as those involved in the noradrenergic system and those associated with the brain stem and locus coeruleus (Bremner, 2003). Extreme trauma may produce oscillation between noradrenergic overactivity and depletion. The stress response system also may interact with the endogenous opiate system to produce effects described next.

In addition to CRF, other neuropeptides and amino acids thought to mediate the stress response include endogenous opioid peptides, neurotensin, somatostatin, cholecystokinin, neuropeptide Y, substance P, vasopressin, and oxytocin. Neuropeptides can function as both hormones (in the body) and neurotransmitters in the central nervous system. Stress is associated with endogenous opiate release, which may be related to the analgesia or numbing produced by the body in stressful situations. Cholecystokinin and neuropeptide Y have been associated with anxiolytic-like responses in several anxiety models (Heilig et al., 1993; Vermetten & Bremner, 2002). Oxytocin and vasopressin play a role in social attachment and may thereby mediate the role of early stressors in producing vulnerability to PTSD.

Glucocorticoids, through their metabolic and immune modulating effects, help the organism maintain homeostasis in the face of stress. Although necessary for survival, persistent elevations in glucocorticoids may damage the central nervous system and physical organs. High levels of cortisol have been associated with damage to the hippocampus in humans, including neuronal loss, inhibited neurogenesis, delayed myelination, and abnormalities in synaptic pruning (Sapolsky, 2000).

Findings related to cortisol in PTSD are not straightforward, however. Some studies find that traumatized children have significantly elevated cortisol levels, relative to controls (DeBellis et al., 1999); others have shown that the pattern of daily cortisol levels varies depending on other factors, including the type of maltreatment experienced by the child and its severity. For example, Cicchetti and Rogosch (2001a) found that children who experienced the most extensive maltreatment, including sexual and physical abuse as well as neglect and emotional abuse, showed significantly elevated morning cortisol levels relative to other maltreated children and to nonmaltreated children. These authors also found that clinical-level internalizing and externalizing symptoms in maltreated and other children were associated with different patterns of cortisol levels and daily fluctuation (Cicchetti & Rogosch, 2001b). Cortisol

findings in adults are different, however, possibly due to the down-regulation of an overly challenged HPA axis. Studies of adults with PTSD have generally found dysregulation of the HPA axis characterized by a blunted response to ACTH and without increased cortisol secretion (DeBellis et al., 1994; Yehuda, 1997).

Neurotransmitters

Catecholamines, including dopamine, and serotonin have been hypothesized to play a role in some of the cognitive features of PTSD, depression, and other anxiety disorders. Dopamine innervation of the medial prefrontal cortex is vulnerable to even mild stress. The medial prefrontal cortex is recognized to play a role in the neuropsychological construct of working memory, with dopamine necessary for its function. This explanation is consistent with neuropsychological studies that suggest that working memory may be impaired in PTSD.

Long-term chronic stressors also result in altered serotonergic functions—an example of the cross-talk and coregulation that exist between the 5HT system and the LHPA axis, two neurobiological systems linked to stress and mood regulation (Lopez, Akil, & Watson, 1999). Animal models suggest that stress increases serotonin turnover in the medial prefrontal cortex, nucleus accumbens, amygdala, lateral hypothalamus, and locus coeruleus. Chronic shock that produces learned helplessness states is associated with reduced serotonin release in the frontal cortex, suggesting that serotonin synthesis is not able to keep pace with demand in this situation (Wu et al., 1999). Supporting this hypothesis are animal studies showing that the capability for increased serotonin metabolism during exposure to inescapable stressors prevents the development of learned helplessness (e.g., Ronan, Steciuk, Kramer, Kram, & Petty, 2000).

The Limbic System

Components of the limbic system, including the hippocampus and amygdala, and closely related structures, such as the orbitofrontal cortex and the anterior cingulate, have been proposed to play a role in the development of PTSD symptoms. The hippocampus is a highly plastic structure. Under stressful conditions, reduced levels of dendritic branching, neuronal loss, and inhibition of neuronal migration in this structure have been reported (Bremner, 2003). Conversely, animal models have demonstrated that administration of selective serotonin reuptake inhibitors (SSRIs) increases dendritic branching and neurogenesis in the hippocampus (Malberg, Eisch, Nestler, & Duman, 2000). Chronic stress also may be associated with potentiated release of norepinephrine in the hippocampus (Nisenbaum,

Zigmond, Sved, & Abercrombie, 1991). It has been suggested that early abuse and neglect affect the maturation of the hippocampus, and it has been hypothesized that this effect accounts for the tendency of abused and neglected children to misinterpret sensory information as more dangerous or threatening than it actually is (van der Kolk, 2003).

Numerous studies have shown that the amygdala is necessary for the establishment of fear conditioning (LeDoux, 1996, 2002). The amygdala rapidly appraises incoming information from the environment and determines whether it constitutes a threat. Projections from the central amygdala initiate the HPA axis response. These projections run from the amygdala to the medulla and hypothalamus and initiate sympathetic and parasympathetic nervous system responses. The amygdala also projects to the brain stem and activates a startle response and other defensive behaviors. Once amygdala circuits are activated and become “trained” through repeated or extreme exposure to fear, they are very hard to modify, and the memories and behaviors associated with them are difficult to extinguish (LeDoux, 1996). Amygdala activation in response to sensory stimuli reminiscent of a trauma then can result in misinterpretation of neutral stimuli as threats. When this occurs, responses are stereotyped and totalistic and prevent new learning from occurring.

Structural and Functional Imaging Studies

The most consistent finding in structural MRI studies of PTSD is reduced hippocampal volume. It is possible that this contributes to memory problems associated with PTSD. Neuroimaging studies of PTSD also implicate regions of the limbic system involved in learning, memory, and emotional regulation (Horner & Hamner, 2002). Several structural MRI studies of Vietnam veterans with PTSD have reported reduced hippocampal volume. Bremner, Randall, Scott, et al. (1995) found right hippocampal volumes to be reduced by 8% in 26 veterans with PTSD, compared with age- and gender-matched healthy controls. Gurvits et al. (1996) reported bilateral volume reductions of 26% in veterans with PTSD relative to healthy controls, even after controlling for age, brain volume, alcohol abuse history, and combat exposure.

Structural MRI studies of individuals who have experienced sexual abuse have produced similar results. In adult survivors of child abuse, Bremner et al. (1997) found 12% reductions in left hippocampal volume compared to matched controls. Stein, Koverola, Hanna, Torchia, and McClarty (1997) reported a 5% reduction in left hippocampal volume versus controls without a history of abuse matched on sociodemographic variables.

It is unclear whether these changes in hippocampal volume are a cause, an effect, or an incidental or nonspecific finding of PTSD. Several animal models suggest, for example, that prolonged glucocorticoid exposure produces hippocampal atrophy (Sapolsky, 2000). In contrast, Gilbertson et al. (2002) question whether hippocampal atrophy is an effect of chronic stress. In a twin study of Vietnam veterans and their twins who were not involved in combat, these researchers found concordance in hippocampal volume of the twins regardless of combat status. This result suggests that reduced hippocampal volume may be an inherited risk factor for PTSD (part of the diathesis), although it could also be a nonspecific finding.

Several functional imaging studies of patients with PTSD have found brain changes that appear to correspond to the emotional reexperiencing symptoms of PTSD (for a review, see Pine, 2003). Symptom provocation designs use visual and script-driven imagery and auditory reminders of traumatic events to trigger reexperiencing symptoms. These studies show decreased functioning in the prefrontal, parietal, and temporal cortex and the hippocampus. Increased activation in the posterior cingulate, motor cortex, amygdala (Rauch et al., 1996; Shin et al., 1999), and anterior cingulate (Liberzon, Abelson, Flagel, Raz, & Young, 1999; Shin et al., 1997) have also been reported, although one recent study using an emotional Stroop paradigm found decreased anterior cingulate blood flow during exposure to emotion words (Bremner, Vermetten, Vythilingam, et al., 2004).

Other Brain- and Nervous System-Level Findings

Physiological hypersensitivity has been found in PTSD patients, which appears to be a result of traumatic exposure and part of the pathophysiology of the disorder (i.e., sensitization of the fear response). PTSD patients show specific signs of increased peripheral physiological responding to both audiovisual and imagined stimuli similar to the traumatic event. Higher heart rate to loud startling tones is one of the most replicated combat-related PTSD findings, and a recent twin study of Vietnam combat veterans has shown this to be an acquired sign of PTSD, as opposed to a preexisting vulnerability (Orr et al., 2003). This exaggerated startle response presumably reflects a sensitization of the fear response (Orr, Lasko, Shalev, & Pitman, 1995). Using an acoustic startle paradigm, Klorman, Cicchetti, Thatcher, and Ison (2003) found that maltreated boys showed smaller increases in amplitude of eyeblink and smaller reductions in blink latency than comparison boys as the startle probe increased in loudness. Although this is not consistent with findings for adult males with PTSD, who exhibit the reverse of these findings, this was inter-

preted as sensitization to noxious stimuli in the maltreated group. This sensitization interpretation is consistent with studies that have shown that at 1 and 4 months posttrauma, individuals with PTSD, compared to those who do not develop the disorder, show greater heart rate responses but lower skin conductance and blunted eyeblink response to startle (Shalev et al., 2000).

Exposure to internal or external trauma cues has been found to produce strong sympathetic reactivity even years after the trauma (Buckley, Blanchard, & Neill, 2000). Results of a study of more than 1,300 Vietnam veterans combined audiovisual and script-driven imagery and found heightened physiologic reactivity to trauma-related cues in the veterans with PTSD (Keane et al., 1998). Such increased arousal is consistent with the fear conditioning model described later, although there are individual differences in psychophysiological responses (Liberzon et al., 1999).

Another possible consequence of trauma is altered brain hemispheric laterality, as shown by functional neuroimaging studies (van der Kolk, 2003). Using a symptom provocation paradigm and PET, Rauch et al. (1996) found pronounced hemispheric lateralization in adults with PTSD who were exposed to reminders of trauma. Teicher, Andersen, Polcari, Anderson, and Navalta (2002) found that patients with a history of abuse in childhood used their left hemisphere predominantly when thinking about neutral memories and their right hemisphere when recalling an early upsetting memory. Control subjects had a more integrated and bilateral response to recalling neutral and traumatic events. In this study, the right hemisphere of the abused participants was as developed as that of control subjects, but their left hemispheric development was arrested. Van der Kolk completed another study with children with trauma histories and found a similar pattern of frontal lobe asymmetry.

In summary, there are several consistent findings at the brain level of research on PTSD. The HPA axis is clearly disrupted by the experience of trauma and/or chronic stress. The size and functioning of the hippocampus and amygdala appear malleable in response to trauma, although the Gilbertson et al. (2002) twin study contradicts this. Physiological hypersensitivity is often found in individuals with PTSD, both adults and children, relative to those without a trauma history. As will be illustrated in the next section, these findings are highly consistent with those found at the neuropsychological level of analysis.

Level 3: Neuropsychology

The neuropsychology of PTSD may be inherently less complex than that of Autism because the causal mechanisms

are clearer, because the epigenetic process of the disorder starts later in development and thus may have less profound consequences, and because the symptoms defining the disorder are less heterogeneous than in Autism and correspond more neatly to traditional neuropsychological domains (i.e., attention, memory, arousal). Perhaps because of this, the neuropsychological research that has been done on PTSD is more focused than that of Autism. It is more closely intertwined with research at the brain level than is Autism research, as the neural mechanisms of fear and stress responses appear to be better understood than the neural mechanisms of the cognitive processes that may mediate autistic symptoms. Over the past decade, the brain level has been where the action is in PTSD research. This creates an opportunity for more basic empirical neuropsychological research as well as studies that integrate findings between the two levels.

This section begins with a review of the extant literature on the neuropsychology of PTSD. Two relatively well-established neuropsychological theories of PTSD—the classical conditioning and the cognitive-behavioral/information-processing models—are then described, with connectionist neural network model of PTSD that is able to incorporate both theories. A discussion of each model's strengths and limitations follows. Criteria used to evaluate neuropsychological theories were set forth in the beginning of this chapter. These include the model's ability to answer questions related to phenotypic variability, external validity, comorbidity, and developmental trajectory. Similar general guidelines to evaluate specific theories of PTSD have been established by Jones and Barlow (1990). These include being able to explain the diverse symptoms of reexperiencing, avoidance, emotional numbing, and persistent arousal, as well as being able to explain individual differences in vulnerability to PTSD symptoms and variability in the severity of symptoms. Brewin, Dalgleish, and Joseph (1996) added several more recommendations, including that the theory explain comorbidities and make novel predictions.

Because several PTSD symptoms appear related to memory processes (both deficient, as in amnesia, and enhanced, as in intrusive memories), most neuropsychological studies of the disorder have focused on memory and/or attention function. More recent work has also explored executive functions, but this area requires further study.

Memory

Studies have explored general memory impairment, performance on list-learning tasks, and trauma-related amnesia. They generally find that PTSD patients of different ages

exhibit deficits in these areas. Although results need to be interpreted with caution due to lack of statistical control for potential confounds, including psychiatric comorbidity, medical illness, and substance abuse, several studies have found that patients with PTSD have deficits in declarative memory for information not related to the trauma (Bremner, Vermetten, Afzal, & Vythilingam, 2004; Horner & Hamner, 2002). Vietnam veterans have been shown to display a pattern of short-term memory impairment (Bremner et al., 1993; Uddo, Vasterling, Brailey, & Sutker, 1993), as have adult survivors of child abuse (Bremner, Randall, Capelli, et al., 1995) and rape (Jenkins, Langlais, Delis, & Cohen, 1998). Autobiographical memory was reduced in inpatient adolescents who had experienced traumas, with high negative correlations between number and severity of traumatic events and the specificity of autobiographical memory (de Decker, Hermans, Raes, & Eelen, 2003). Yehuda et al. (1995) found that adult veterans with PTSD exhibited memory deficits as assessed by a list-learning task. Compared with control subjects, individuals with PTSD showed a significant reduction in retention of previously learned lists when a distracting intervening list was presented. This was interpreted as compatible with the idea that intruding thoughts or flashbacks produced declarative memory deficits. Although intrusions and amnesia appear to be opposite problems, they may be related in that intrusive memories may interfere with the capacity to process other material.

Moradi, Doost, Taghavi, Yule, and Dalgleish (1999) studied children ages 11 to 17 with PTSD using the Rivermead Behavioral Memory Test (Wilson et al., 1998), a measure of memory in everyday contexts. They found that children with PTSD were significantly impaired relative to a control group on a global measure of memory. Clark et al. (2003) explored working memory for neutral verbal information using PET technology and a task requiring detection of different colored target words. They found that individuals with PTSD showed significantly less activation in the left dorsolateral prefrontal cortex, which is typically involved in monitoring and manipulating working memory content.

Both the incidence and the mechanism of amnesia in PTSD remain controversial. One study reported that more than 30% of adults who were sexually abused as children were amnesic about the abuse for many years (Williams, 1994), but this study has been criticized on methodological grounds, and the concept of repressed memories of abuse is hotly debated (see McNally, 2003). Brewin et al. (1996) have conceptualized amnesia as the absence of verbally accessible knowledge, leaving only unconscious, situationally

accessible knowledge available. In this model, amnesia is the result of a strategy to avoid trauma-related stimuli by not attending to the negative emotions associated with the trauma. However, McNally, Metzger, Lasko, Clancy, and Pitman (1998) found that in a directed forgetting task, children with PTSD exhibited recall deficits for positive and neutral words only, as opposed to trauma-related words. Factors related to depth of encoding and retrieval, including the degree of elaboration, organization, and rehearsal of memories, may also play a role in the forgetting of unpleasant trauma-related memories (Koutstaal & Schacter, 1997).

Attention and Executive Function

Neuropsychological studies of attention in PTSD have adopted several approaches. Research in this area has examined such components of attention as sustained attention, learning of new material, shifting attention, and ideational fluency, as well as issues of attention allocation and bias.

Vasterling, Brailey, Constans, and Sutker (1998) studied Gulf War veterans with PTSD and a control group without PTSD who had also participated in combat in this war. Significant sustained attention, mental manipulation, initial acquisition of information, and retroactive interference differences were observed between the groups, as were errors of commission and intrusion. Results suggested that trauma-related intrusions may reflect a more general pattern of disinhibition. This study also found that disinhibition and intrusions on cognitive tasks correlated positively with reexperiencing symptoms and negatively with avoidance and numbing symptoms. Vasterling et al. (2002) found that Vietnam veterans with PTSD scored significantly worse than Vietnam veterans without PTSD on tasks of sustained attention, working memory, and learning, but not on focused attention or shifting attention measures. These findings were independent of intellectual functioning.

Beers and DeBellis (2002) found that children with PTSD made significantly more errors on measures of freedom from distractibility, including the Stroop Color Word Test. They also made more omission errors on a test of sustained attention. Shields and Cicchetti (1998) found attention deficits in maltreated children ages 6 to 12 relative to controls.
